The quantity ϕ^{bcd} in (77) gives the hydraulic head in the soil for cases b, c and d of Figure 2; and ϕ^{aefg} for cases $aefg$ of the same figure.

Formulas for the hydraulic head in a submerged drain tube—In the last section we have seen that a drain tube which has the shape of an equipotential enclosing a slit sink in Figures 2a, 2e, 2f, and 2g will not ordinarily intercept the x-axis. Therefore the hydraulic head over such a sink will be negative. In particular, the hydraulic head at all points on a (nearly) circular drain tube of Figure 2g, whose circumference includes a point $(x, y) = (r, c)$, is obtained from expression (78) by changing (x, y) to (r, c) with the result

$$\phi^{g}(r, c) = \frac{2sR}{k}\frac{1}{\pi}[V^{g}(r, c) - V^{g}(0, 0)] \quad (79)$$

Similarly for Figure 2f we find

$$\phi^{f}(r, h) = \frac{2sR}{k}\frac{1}{\pi}[V^{f}(r, h) - V^{f}(0, 0)] \quad (80)$$

We point out (an important matter in applying (79) and (80)) that unless in (79) the value of r is such that $\phi = -c$, the drain tube will have to be under suction or pressure in order for the theoretical conditions to be realized and hence for (79) to be valid. A similar statement holds for (80). To keep this paper within bounds, (79) and (80) will not be further discussed.

Height of water table—Put $y = 0$ in (77) to obtain the height $\phi^{bcd}(x, 0)$ ($= z$ of Figures 2b, c, d) of the water table above the reference level. The result is

$$\phi^{bcd}(x, 0) = \frac{2sR}{k}\frac{1}{\pi}[V^{bcd}(x, 0) - V^{bcd}(r, 0)] \quad (81)$$

Similarly from (78)

$$\phi^{aefg}(x, 0) = \frac{2sR}{k}\frac{1}{\pi}[V^{aefg}(x, 0) - V^{aefg}(0, 0)] \quad (82)$$

Putting $x = s$ in (81) and (82) gives for their left-hand sides the height H of the cases in Figure 2.

Case d is of particular interest. For it we have from (81) (with z^d used for $\phi^d(x, 0)$)

$$z^d = \frac{2sR}{k}\frac{1}{\pi}[V^d(x, 0) - V^d(r, 0)] \quad (83)$$

or in elemental terms, using (49), (34), and (29) with (83) and simplifying with the aid of *Dwight* [1947, formula 403.4]

$$z^d = \frac{2sR}{k}\frac{1}{\pi}\left[\ln\frac{\sin(\pi x/2s)}{\sin(\pi r/2s)} + \sum_{m=1}^{\infty}\frac{1}{m}\left(\cos\frac{m\pi r}{s} - \cos\frac{m\pi x}{s}\right)\frac{e^{-m\pi h/s}}{\sinh(m\pi h/s)}\right] \quad (84)$$

where in numerical computations one should use, to save work, the identity

$$e^{-m\pi h/s}/\sinh(m\pi h/s) = \coth(m\pi h/s) - 1 \quad (85)$$

(Another useful computational hint for (84) is to obtain natural logarithms by reading a table of exponential values inversely. ***Holtappel's*** [1938] tables are especially valuable for practical work, as they can be read inversely to give ln x to three or four significant figures without interpolation. Thus $\ln 22.07 = 3.094$ from ***Holtappel***, [*p.* 21].)

The maximum height H of the water table is obtained by putting $x = s$ in (84). The result is, utilizing (85) and noting for practical work that $\sin(\frac{1}{2}\pi r/s) = \frac{1}{2}\pi r/s$

$$H^d = \frac{2sR}{k}\frac{1}{\pi}\left[\ln\frac{2s}{\pi r} + \sum_{m=1}^{\infty}\frac{1}{m} \cdot \left(\cos\frac{m\pi r}{s} - \cos m\pi\right)\left(\coth\frac{m\pi h}{s} - 1\right)\right] \quad (86)$$

From (86) we see that the maximum water-table height is directly proportional to R/k, the ratio of rainfall to soil hydraulic conductivity. Thus doubling the rainfall rate doubles the water table height. The same statement holds for Figures 2b and 2c. In (86) we see that H^d is not directly proportional to $2s$ because $2s$ is involved in the logarithm term, and in the sum terms, as well as being a factor of the whole right-hand side.

If in (86), $h/s \to \infty$; that is, if the impermeable layer is at great depth, with s staying finite, then (86) reduces to the very simple result

$$H^d \text{ (for } h/s \to \infty) = (2sR/k)(1/\pi)\ln(2s/\pi r) \quad (87)$$

which is independent of the (great) depth h, as it should be. Since in (87), $\ln(2s/\pi r)$ varies very slowly compared to s, we can say, for practical purposes, that for the case of Figure 2d doubling the tile spacing will double the height H in the figure of the water table for the same rainfall. This statement is true if the soil is of uniform hydraulic conductivity to great depth and if no drainage water seeps away at the great depth.

In (86) let F be defined by

$$F = \frac{1}{\pi}\left[\ln\frac{2s}{\pi r} + \sum_{m=1}^{\infty}\frac{1}{m} \cdot \left(\cos\frac{m\pi r}{s} - \cos m\pi\right)\left(\coth\frac{m\pi h}{s} - 1\right)\right] \quad (88)$$

Then (86) becomes

$$H^d = (2sR/k)F(2r/2s,\, h/2s) \quad (89)$$

where we have shown F as a function of $2r/2s$ and $h/2s$ rather than of say r/s and s/h because the ratios $2r/2s$ and $h/2s$ are convenient in practice. To facilitate computation of H^d, a table of F has been prepared and is given as Table 1.

We see from the table, for example, that if $2s = 100$ ft and $h = 4$ ft, so that $h/2s = 0.04$; and if $2r = \frac{1}{2}$ ft, so that $2r/2s = 0.005$, the value of H will be $H = (100R/k)$ (3.643). Accordingly, if the rainfall rate is $\frac{1}{2}$ in/day and the hydraulic conductivity 96 in/day, we find $H = 1.90$ ft.

Fall of the water table when rain ceases—At the instant rainfall ceases the rate of fall of the water table can be computed, since this rate will be the vertical velocity ('velocity' in the Darcy law sense) computed at $y = 0$ divided by the fraction p of drainable pore space. Since the vertical velocity at any point in the soil is

$$-k\partial\phi/\partial y = -\partial\Phi/\partial y$$

the rate of fall G midway between drain tubes ($x = s$) is

$$G = -(1/p)[\partial\Phi/\partial y]_{x=s,\,y=0} \quad (90)$$

where Φ is as in (13). The formula (90) can only be used at the instant rainfall ceases, because after that instant the potential distribution will have changed and will continue to change until flow ceases. Evaluation of the RHS of (90) yields, as it physically should, the result R/p; this is the same result found when the subscript $x = s$ is changed to $x = x$ in the equation.

FLOW NETS

Three flow nets (Fig. 3) corresponding to Figures 2bcd have been calculated. Eq. (40), (43), and (47) were used for the streamlines and (77) for the lines of equal hydraulic head or equipotentials. The net function in each case is expressed in per cent.

In each net the lowest point of the water table is taken to be four feet below the soil surface and the impervious layer is at a 14-ft depth. Therefore the theoretical flow region is of height $h = 10$ ft for all three nets. The semispacing s for all three nets is 50 ft to yield a realistic drain spacing $2s = 100$ ft. A value of R/k was chosen ($= 0.01087$) to make $H = 2.000$ ft in the d part of Figure 3. For Figures 3b and 3c the values of H for this value of R/k turned out to be 1.874 ft and 1.330 ft.

TABLE 1 – *Values of $F(2r/2s, h/2s)$ of (88) and (89) for computing the maximum height H ($= H^d$) of the water table for Figure 2d, with R the rainfall rate and k the hydraulic conductivity (R and k in the same units, say inches per day); multiply the entries by $2sR/k$ to obtain the height H, in the units used for s*

0.32	1.787	1.566	1.345	1.125	0.9040
0.64	1.764	1.543	1.323	1.102	0.8811
1.00	1.763	1.543	1.322	1.101	0.8808
∞	1.763	1.543	1.322	1.101	0.8808

In Figure 3b the equipotential passing through the point $x = r = (1/20)h = 0.5$ ft and $y = 0$ was identified with the ditch (at potential zero) so that the semi-width of the ditch in Figure 3b is 0.5 ft. The slit depth d was taken to be one foot. Therefore the depth of the ditch is somewhat greater than one foot (1.04 ft). The zero equipotential approximates closely the shape of a ditch one might find in practice.

In Figure 3c the equipotential passing through the point $x = (1/20)h = 0.5$ ft and $y = 0$ was also identified with the ditch. But here the theoretical ditch does not look like a real one. Its walls slope in the wrong direction. Nevertheless it is clear from physical intuition, and more specifically from the small changes in the values of the three computed negative equipotentials shown in the lower left of the net, that changing the slope of the walls of the ditch to make its shape approximate the shape of a real ditch would only influence the flow net slightly. Therefore the flow net of Figure 3c may be taken to represent the flow net for drainage by a real ditch, flowing with water in it to the level of the water table, $y = 0$, and penetrating down to an impermeable layer, $y = h$.

In Figure 3d the equipotential passing through the point $(x, y) = (r, y) = (0.05h, 0)$ was again chosen to be the zero equipotential and verifies that the zero equipotential, as was indicated in Figure 2d, is a semicircle. In fact the equipoten-

Fig. 3 – Flow nets b, c, and d corresponding to cases b, c, and d of Figure 2 when a full-flowing ditch or half-filled drain tube is identified with a surface of equal hydraulic head surrounding a slit or line sink; the water table heights shown are for a rainfall-hydraulic conductivity ratio $R/k = 0.01087$ for each net

tials for some distance away from the drain center are semicircles, or nearly so, as they should be.

Above each of the flow nets are shown curves of the variation with distance from the drains of the height of the water table, corresponding respectively to the maximum heights 2.000, 1.874 and 1.330 ft. Since the ratio $R/k = 0.01087$ to produce these heights is approximately 0.01 one may interpret the water tables to correspond to an average rainfall of about 0.1 inches per day for a soil of hydraulic conductivity $k = 10$ in/day. When it is remembered that the depths of the drains for Figures 3d, 3b and 3c are, respectively, 0.5 ft, 1.04 ft, and 10 ft, it becomes clear that the corresponding maximum water table heights, 2 ft, 1.874 ft, and 1.330 ft are not sensitive to the shape of the drain. This statement is true only if each drain has water standing in it to the level $y = 0$.

From (81) (with $x = s$ and $r = 0.05h$) it is seen that the equipotentials of Figures 3b, 3c, and 3d have involved the computation of the differences $V^b(s, 0) - V^b(0.05h, 0)$ etc to correspond to equipotential differences of 100 pct. To relate the values of the equipotentials, as given in percentages on the nets, to the basic computed numbers, which were obtained with considerable labor, the following computed values (with $s = 50$ and $h = 10$) are given: $V^b(50, 0) = 1.4137$; $V^b(0.5, 0) = -4.0018$; $V^c(50, 0) = 1.4137$ (the same value to four decimals as $V^b(50, 0)$); $V^c(0.5, 0) = -2.4300$; $V^d(50, 0) = 1.414$; $V^d(0.5, 0) = -4.364$. For Figure 3b, the difference in potential, 100 percent, corresponds therefore to $[1.4137 - (-4.0018)] = 5.4155$; for Figure 3c, 3.8437; and for Figure 3d, 5.778. The numbers 5.778, 5.4155 and 3.8437 are in direct proportion to the previously given water table heights, 2 ft, 1.874 ft, and 1.330 ft, respectively.

THE THEORY COMPARED WITH FIELD DATA

Kirkham and De Zeeuw [1952] have obtained, in replicated field experiments, and under average steady rainfall conditions, water-table shapes for 8- and 16-meter spacing of tube (tile) drains; and maximum heights of water tables for 8-, 10-, 12-, and 16-meter spacings, both for tile and ditch drains. We may compare the theory with their results. In the following the numbers in parentheses refer to the page number in the [1952] reference. The drain tiles were of 7 cm outside diameter (p. 286), with their measured centers averaging 93.5 cm (p. 287) below the soil surface. The tiles were installed on a trench bottom of average measured depth 97 cm (p. 287). The trench bottom when made was nominally 14 cm wide (p. 286) and when the tiles were in place the trench was back-filled to a height 15 cm above the trench bottom with a highly permeable material fabricated from oligotrophic peat (p. 292). Thus, the tile lines likely behaved as if they were of greater outside diameter than 7 cm. We take the diameter to be 9 cm, a figure which need not be exact because we have seen by (84) and (86) (compare also Fig. 3) that tube diameter enters in the theory logarithmically and hence changes in tile diameter will not influence results greatly. But it would be wrong to take the tile diameter equal to the width, 14 cm, of the porous peat backfill, even if the porous peat were infinitely permeable, because the peat was not placed beneath the tile.

An impermeable layer was at 180 cm depth (p. 287) and the average hydraulic conductivity of the soil in the flow region (see their Fig. 4) was about 50 to 150 mm/day, varying with depth. The rainfall averaged 2.82 mm/day (p. 290) for the 13-day test period, Nov. 27 to Dec. 9, 1950 (p. 290). Evapotranspiration averaged 0.40 mm per day from Nov. 24 to Dec. 14 (p. 293) and we assume the same value 0.40 mm for the test period Nov. 27 to Dec. 9. Test wells for measuring water-table height were located (p. 287) at positions 0.18, 1, 2, and 4 meters from the tile centers for the 8-meter spacing of tiles. The water-table distance below the soil surface at these positions averaged (see their Fig. 7), respectively, 84.9, 74.1, 65.9, and 60.4 cm. For the 16-meter spacing the test wells (p. 287) were 0.18, 1, 2, 4, and 8 meters from the tile centers, and the water-table distance below the soil surface at these respective wells averaged 82.4, 62.7, 48.3, 28.1, and 15.5 cm. The depth of the water table midway between 8-, 10-, 12-, and 16-meter spaced tile drains was (see their Fig. 6), respectively, 60.4, 48.3, 28.1, and 15.5 cm. The depth of the water table midway between 8-, 10-, 12-, and 16-meter spaced tile drains was (see again their Fig. 6), respectively, 60.4, 47.3, 37.2, and 15.5 cm. Corresponding figures for the (same spaced) ditch drains are 39.9, 35.0, 26.2, and 7.7 cm. The ditches were of trapezoidal shape (p. 286), nominally 60 cm deep, 25 cm wide at the bottom, and 115 cm wide at the top. The ditches were full of water (p. 290) to 50 cm depth and because of uncleanness we assume them to have been 55 cm deep. We further assume, in order to use the theoretically simple cases of Figure 2d, that the ditch bottoms were of effectively semicircular cross section with centers 50 cm from the soil surface and radii 9 cm. We have seen in Figure 3 that heights of water tables are not very sensitive to shapes of the ditches. By subtracting the tile center depth from the water table depths, etc., we have made a table of values (Table 2) from the above data to test the theory (Figures 4A and 4B).

In Figure 4A, which is for tile drains, the theoretical curve is obtained from the right-hand side of (84) utilizing the experimental values $R = 2.42$ mm per day, $k = 100$ mm per day, $2s = 8$ meters, $r = 4.5$ cm and $h = 86$ cm. The data fit the curve unexpectedly well.

TABLE 2 – *Data of field drainage experiments of Kirkham and DeZeeuw [1952] tabulated in notation of Figure 2d of present paper*

Drain type[a]	Spacing (2s)	x	z	H
	m	m	cm	cm
Tile drains with r = 4.5 cm and h = 86 cm	8	0.18	8.6	33.1
	8	1.0	19.4	33.1
	8	2.0	27.6	33.1
	8	4.0	33.1	33.1
	10			46.2
	12			56.3
	16	0.18	11.1	78.0
	16	1.00	30.8	78.0
	16	2.00	45.2	78.0
	16	4.00	65.4	78.0
	16	8.00	78.0	78.0
Ditch drains[b] with r = 9 cm and h = 86 cm	8			10.1
	10			15.0
	12			23.8
	16			42.3

[a] For both tile and ditch drain plots, the net precipitation R (rainfall less evapotranspiration) was $R = 2.82 - 0.40 = 2.42$ mm/day; and the hydraulic conductivity of the soil varied from k = 50 mm/day to about k = 150 mm/day [see *Kirkham* and *DeZeeuw*, 1952, Fig. 5].

[b] The ditches are assumed to have an equivalent semicircular bottom of radius 9 cm; see text.

In Figure 4B, which is for open ditches, notice that the ratio R/k is taken as 0.0121, just half the value for Figure 4A. The use of a lower value of R/k here is probably justifiable for two reasons. In the first place, of the 2.42 mm per day of precipitation, some of it must have run off into the ditches making the effective R in R/k less than 2.42 mm per day. Secondly, the data of Kirkham and De Zeeuw show that the hydraulic conductivity is higher for the ditch drainage case than for tile drains, making R/k smaller, since the ditches are located higher in the soil where hydraulic conductivity values up to 200 mm per day were sometimes measured (see their Fig. 5) That a value of R/k occurs for the ditches which is just half that for the drains must be considered as fortuitous. Theory and experiment agree fairly well in Figure 4B.

Comparisons with the theory for z versus x values for the 16-meter drain data of Table 2 are not made since the ratio H/h = 78.0/86 is too large for the theory to be expected to hold. The theory is strictly accurate only as H/h approaches zero. Also, because H/h is not small, a theoretical graph of the relation of H to 2s for the 8- to 16-meter spacing of tiles is not presented. Some calculations have, however, been made. They show that the theory fits the experimental points increasingly poorly as H/h increases from the experimental values 33.1/86 to 78.0/86. In fact, corresponding to 2s = 8, 10, 12, and 16 meters, the theory yields (for k = 100 mm per day and R = 2.42 mm per day as for Figure 4a) the values 33.6, 49.5, 67.3, and 112.3 whereas the corresponding experimental values shown in Table 2 are 33.1, 46.2, 56.3, and 78.0 cm. Only the experimental values 33.1 and 46.2 compare well with the theoretical ones 33.6 and 49.5.

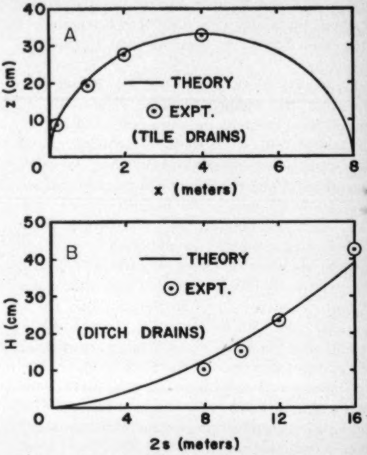

FIG. 4 – Comparison of theory, for the case of Figure 2d (see it for symbols) with experimental field data of *Kirkham* and *De Zeeuw* [1952]; (A) height of water table z versus distance x from tiles, when r = 4.5 cm, h = 86 cm and R/k = 0.0242; (B) midpoint height H of water table versus spacing 2s of semicircular ditches when r = 9 cm, h = 130 cm and R/k = 0.0121; R is rainfall rate; k is soil hydraulic conductivity

It is to be noticed that the experimental data which are compared here with the theory are actual field data, not laboratory model data.

DERIVATION OF DUPUIT-FORCHHEIMER (DF) THEORY

Although *Muskat* [1946, esp. p. 361] has pointed out "the inconsistencies of the Dupuit assumptions with the direct implications of Darcy's law," nevertheless Forchheimer and others have used the theory extensively in application to practical seepage problems. A particularly disturbing implication of the DF theory is that it does not provide for convergence of flow in the vertical direction and hence the shape and size of horizontal tiles and ditches into which the water seeps do not enter into the theory at all. Because of the above matters it was a surprise to discover that the present theory reduces, under special conditions, to DF theory and that accordingly the DF theory is justified for these special conditions, as will be seen.

To derive the DF theory from our theory we refer to (86) and state the special conditions, which are that $r/s \to 0$, that $h/s \to 0$ and that the water table approaches flatness. That is, we will show that (86) goes over to DF theory, provided s is very large compared to r and h in Figure 2d and if the water table approaches flatness.

Let us first consider the sum in (86). In the first place we notice that since the sum converges we can obtain any desired degree of accuracy by summing only for $m = 1, 2, 3, \ldots, M$ where M is finite. Now let us assume that r/s and h/s are sufficiently small, that $\cos (m\pi r/s) \to 1$, and in view of *Dwight* [1947, formula 676.6], that $[\coth (m\pi h/s - 1] \to [s/(m\pi h) - 1] \to s/(m\pi h)$. Then the sum $\sum_1^\infty$ in (86) becomes, if M is taken large enough,

$$\sum_1^\infty \to \sum_1^M \frac{1}{m} (1 - \cos m\pi) \frac{s}{m\pi h} \qquad (m = 1, 2, 3, \cdots)$$

$$= \frac{2s}{\pi h} \sum_1^M \frac{1}{m^2} \to \frac{2s}{\pi h} \sum_1^\infty \frac{1}{m^2} \qquad (m = 1, 3, 5, \cdots)$$

$$= \frac{2s}{\pi h} \frac{\pi^2}{8} = \frac{\pi s}{4h}$$

where we have utilized *Dwight* [1947, formula 48.4].

Formula (86) now becomes, approximately, after the dropping of the superscript d

$$H = \frac{2sR}{k} \frac{1}{\pi} \left[\ln \frac{2s}{\pi r} + \frac{\pi s}{4h} \right] \to \frac{2sR}{k} \frac{1}{\pi} \frac{\pi s}{4h}$$

provided $s \to \infty$ and other quantities stay finite. That is, we have finally when $s \to \infty$

$$H = \frac{2sR}{k} \frac{s}{4h}, \qquad (s \to \infty) \tag{91}$$

which is independent of the drain size and is, as we shall see, nothing but the DF result for Figure 2d if $H \to 0$.

Since (91) is independent of drain size and hence also of drain shape, we can assume that the drain is a ditch drain of depth h to the impervious layer. (But remember that the ditch to be compatible with the preceding work must have water standing in it to a height h.) Now in (91) let Q_1 be the flow entering a drain from one side and let $H_0 = H + h$. Then (91) may be written in the form

$$s = 2kh(H_0 - h)/Q_1 \tag{92}$$

Now if h is the height of water in a ditch or drain, and if H_0 is the height of the water table midway between drains (h and H_0 both being heights above the impermeable layer) and if s is the semispacing of drains, the conventional DF theory yields (see for example *Van Schilfgaarde* and others [1956])

$$s = k(H_0^2 - h^2)/Q_1 \tag{93}$$

To show that (92) and (93) are equivalent when the water table approaches flatness we write (93) as

$$s = k(H_0 + h)(H_0 - h)/Q_1 \tag{94}$$

or since $(H_0 + h) \to 2h$ when the water table approaches flatness, we see that (94) becomes

$$s = 2kh(H_0 - h_0)/Q_1 \tag{95}$$

which is precisely (92).

Since (92) was derived by rigorous methods and is exact insofar as the water table approaches flatness and $s \to \infty$ (with h and r being finite) then (95), the DF theory, is also exact if $s \to \infty$ and the water table approaches flatness. In other words, a rational basis for the DF theory has been obtained. Notice that as the water table approaches flatness there can be no surface of seepage, so (92)–(95) do not involve the complication of surfaces of seepage.

Although DF theory implies when $h/s \to 0$ that drain size makes no difference in H, notice in Table 1, row 1, that with $h/2s$ as small as 0.01 (for example, $h = 4$ ft, $2s = 400$ ft) the radius of the drain still makes an appreciable difference in F and hence in H of (86) or (89). In fact, for $2r/2s = 0.0025$ and 0.04 we find from Table 1 and (89), using obvious notation

$$H_{0.0025}/H_{0.04} = 12.79/11.52 = 1.11$$

or a height difference of 11 percent due to the drain size difference. If $h/2s$ were increased from 0.01 to 0.04 the corresponding result would be,

$$H'_{0.0025}/H'_{0.04} = 3.864/2.954 = 1.31$$

or a height difference of 31 percent due to the drain size difference. Thus for most practical situations use of DF theory will result in an appreciable error.

CONCLUSIONS

Use of exact mathematical methods, together with a justified simplifying physical assumption, have enabled the derivation of formulas for (a) flow nets, (b) the maximum height of the water table, (c) the variation of the water-table height with distance from a drain, and (d) rate of fall of the water-table at the instant rainfall ceases, for seven different cases of tube and ditch drains, when steady rainfall seeps at a steady rate through homogeneous soil to the drains. Water-table heights computed by the formulas agree with water table heights found in field experiments. The theory yields the Dupuit-Forchheimer (DF) theory for the special case that the water table is nearly flat and that the drain spacing is very large compared to a depth of an impermeable layer on which the water-saturated soil rests. Thus a rational basis for DF theory is provided. In practice DF theory should not be used unless the very special conditions for which it becomes valid are realized.

APPENDIX I—PROOF OF CERTAIN FORMULAS

In the proofs below we have assumed, without proof, that the mathematical procedures used would work. For example we have used formulas for functions of real variables, as if the formulas also hold for complex variables, without so proving. That our procedures have been valid has always been checked by numerical tests of the end results. We have not specified in all cases the range of validity of the formulas. Numerical calculations (and analysis not given here) show that the formulas are valid at least for the range of variables in our problem.

In all the summations below it is to be understood that the index of summation is m and that m is to have the value $m = 1, 2, 3, \ldots, \infty$.

Proof of (23) *and* (24)—We need only prove (23), since (24) may be written down by inspection of (17), (19), and (23).

To prove (23) we compare it with (17) and, letting $A = \pi x/s$ and $B = \pi y/s$, we see that our task is: Prove

$$S_1 = \sum \frac{\sin mA e^{-mB}}{m} = \tan^{-1} \frac{\sin A}{e^B - \cos A} \qquad (96)$$

Proof—Substitute the exponential form for the sine [*Dwight*, 1947, formula 408.01] into the first equality in (1), rearrange, and find

$$S_1 = \frac{1}{2i} \sum \frac{e^{m(Ai-B)}}{m} - \frac{1}{2i} \sum \frac{e^{-m(Ai+B)}}{m} \quad ,$$

Next, expand the sums and, utilizing Dwight 601.1, with Dwight's x first equal our $e^{(Ai-B)}$ and then equal our $e^{-(Ai+B)}$ find

$$S_1 = -\frac{1}{2i} \ln \frac{1 - e^{Ai-B}}{1 - e^{-(Ai+B)}} = -\frac{1}{2i} \ln \frac{e^B - e^{Ai}}{e^B - e^{-Ai}}$$

Now use Dwight 408.04 to find

$$S_1 = -\frac{1}{2i} \ln \frac{(e^B - \cos A) - i \sin A}{(e^B - \cos A) + i \sin A}$$

Now represent the numerator of the argument of the logarithm by the vector $Re^{i\theta}$ where R is the magnitude of the vector and θ the angle the vector makes with the real axis. Then

$$e^B - \cos A - i \sin A = Re^{i\theta}$$

where we must have

$$R = [(e^B - \cos A)^2 + \sin^2 A]^{\frac{1}{2}}$$

and

$$\tan \theta = -\sin A/(e^B - \cos A)$$

Similarly we may denote the denominator of the argument of the logarithm by $R'e^{i\theta'}$ where we find

$$R' = R \text{ and } \theta' = -\theta$$

Accordingly

$$S_1 = -\frac{1}{2i} \ln \frac{Re^{i\theta}}{Re^{-i\theta}} = -\frac{1}{2i} \ln e^{2i\theta}$$

or

$$S_1 = -\frac{1}{2i} (2i\theta) = -\theta$$

That is, finally

$$S_1 = \tan^{-1} [\sin A/(e^B - \cos A)]$$

and (96) is proved.

Expression (96) is valid at least for $0 \leqq A \leqq 2\pi$ if B > 0; and is valid for $0 < \mathrm{A} < 2\pi$ if B $= 0$.

Proof of (34) *and* (35)—We need only prove (34), since (35) follows from (29) by inspection of (28) and (34). To prove (34) we compare it with (28); letting $A = \pi x/s$, $B = \pi y/s$, we see that our task is: Prove

$$T_1 = \sum \frac{1}{m} \cos mA e^{-mB}$$
$$= -\tfrac{1}{2} \ln [2e^{-B} (\cosh B - \cos A)] \qquad (97)$$

Proof—Using Dwight 408.02 in the first of (97), find

$$T_1 = \tfrac{1}{2} \sum \frac{e^{m(Ai-B)}}{m} + \tfrac{1}{2} \sum \frac{e^{-m(Ai+B)}}{m}$$

So that by Dwight 601.1

$$T_1 = -\tfrac{1}{2}\ln\left(1 - e^{Ai-B}\right) - \tfrac{1}{2}\ln\left(1 - e^{-(Ai+B)}\right)$$

$$= -\tfrac{1}{2}\ln\left[e^{-B}\left(e^{B} + e^{-B} - e^{Ai} - e^{-Ai}\right)\right]$$

or by Dwight 654.2 and 408.02

$$T_1 = -\tfrac{1}{2}\ln\left[2e^{-B}(\cosh B - \cos A)\right]$$

which is (97), and completes the proof.

Proof of (62) and (63)—To prove (62) we see from (56) and (62), that if we let $\pi y/h = \alpha$ and $\pi x/h = \beta$, our task becomes: Prove that

$$S_b^f = \sum (-1)^m \frac{1}{m}\sin m\alpha e^{-m\beta}$$

$$= -\tan^{-1}\frac{\sin\alpha}{e^{-\beta} - \cos\alpha} + \tan^{-1}\frac{\sin 2\alpha}{e^{-2\beta} - \cos 2\beta} \qquad (98)$$

It is first left to the reader to demonstrate (by expanding and then regrouping terms) that if

$$f(m) = \sin m\alpha e^{-m\beta}$$

then

$$\sum (-1)^m \frac{f(m)}{m} = -\sum\frac{f(m)}{m} + \sum\frac{f(2m)}{m} \qquad (99)$$

The sums on the right are known from (96); whence (98) follows immediately, which was to be proved.

To prove (63) it must be proved that the RHS of (58) is equal to the RHS of (63). Let $A' = \pi y/h$ and $B' = \pi x/h$. Then we must prove that

$$\sum (-1)^m \frac{1}{m}\cos mA' e^{-mB'}$$

$$= \tfrac{1}{2}\ln\left[2e^{-B'}(\cosh B' - \cos A')\right]$$

$$- \tfrac{1}{2}\ln\left[2e^{-2B'}(\cosh 2B' - \cos 2A')\right] \qquad (100)$$

Proof—First observe that (99) is valid if $f(m) = \cos mA'\, e^{-mB'}$. Then use (97) to find that (100) follows immediately.

Proof of (71) and (72)—We first consider (71). Upon comparing (65) and (71) one sees, with $\alpha = \pi y/h$ and $\beta = \pi x/h$, $\gamma = \pi c/h$, that our task is: Prove

$$S_b^g = \sum\frac{1}{m}\cos m\gamma \sin m\alpha e^{-m\beta}$$

$$= \tfrac{1}{2}\tan^{-1}\frac{\sin(\alpha+\gamma)}{e^{\beta} - \cos(\alpha+\gamma)}$$

$$+ \tfrac{1}{2}\tan^{-1}\frac{\sin(\alpha-\gamma)}{e^{\beta} - \cos(\alpha-\gamma)} \qquad (101)$$

Proof—By Dwight 401.05

$$\sin m\alpha \cos m\gamma = \tfrac{1}{2}[\sin m(\alpha+\gamma) + \sin m(\alpha-\gamma)]$$

So that

$$S_b^g = \tfrac{1}{2}\sum\frac{1}{m}\sin m(\alpha+\gamma)e^{-m\beta}$$

$$+ \tfrac{1}{2}\sum\frac{1}{m}\sin m(\alpha-\gamma)e^{-m\beta}$$

But the sums in S_b^g may be written down by use of (96); whence (101) follows immediately, which was to be proved.

To prove (72), we see comparing (67) and (72), and with α, β, and γ as above, that our task is: Prove

$$T_b^g = \sum\frac{1}{m}\cos m\gamma \cos m\alpha e^{-m\beta}$$

$$= -\tfrac{1}{4}\ln\{2e^{-\beta}[\cosh\beta - \cos(\alpha+\gamma)]\}$$

$$- \tfrac{1}{4}\ln\{2e^{-\beta}[\cosh\beta - \cos(\alpha-\gamma)]\} \qquad (102)$$

Proof—By Dwight 401.06

$$\cos m\alpha \cos m\gamma = \tfrac{1}{2}\cos m(\alpha+\gamma) + \tfrac{1}{2}\cos m(\alpha-\gamma)$$

so that

$$T_b^g = \tfrac{1}{2}\sum\frac{1}{m}\cos m(\alpha+\gamma)e^{-m\beta}$$

$$+ \tfrac{1}{2}\sum\frac{1}{m}\cos m(\alpha-\gamma)e^{-m\beta}$$

The sums on the right may be written down immediately from (97), whence (102) follows immediately, which was to be proved.

Simultaneous Transfer of Heat and Moisture in Porous Media

D. A. DE VRIES

Abstract—Simultaneous differential equations for the transfer of heat and moisture in porous media under the combined influence of gravity and gradients of temperature and moisture content are developed. These equations are a generalization of those derived by *Philip* and *de Vries* [1957]. In particular a consistent distinction is made between changes of moisture content in the liquid and the vapor phase.

The interaction between heat and moisture transfer in steady state heat conduction is discussed in detail using numerical values for two soils, a clay loam and a medium sand. The behavior is found to be dependent on the boundary conditions for moisture transfer, on the direction of the temperature gradient and on the ratio of two moisture diffusivities entering in the analysis.

Introduction—In a recent paper *Philip* and *de Vries* [1957] discussed the movement of liquid water and water vapor in porous media under the influence of gradients of temperature and moisture content. In the final paragraph of that paper they presented equations of simultaneous heat and moisture transfer. The present paper extends this approach.

In particular heat transfer by moisture movement is considered in greater detail. Heat of wetting and transfer of sensible heat are taken into account. Furthermore a consequent distinction is made between changes of moisture content in the liquid and the vapor phase, whereas in the final paragraph of the paper cited it was tacitly assumed that changes of moisture contained in the vapor phase are negligible. This may often be admissable, because the vapor content is usually small in comparison with the liquid content (both expressed as g/cm^3). However, there are also many situations where changes in liquid and vapor content can be of the same order. This will be so in particular where these changes are due to moisture movement under the influence of temperature gradients. A number of implications of the new equations will be discussed using numerical data for a coarse textured and a medium textured soil.

Notation—The notation in the present paper is almost the same as that of the paper cited. The most important difference is that the symbol θ is used here to denote the total moisture content (liquid + vapor), whereas in the previous paper it stood for liquid moisture content. For reasons of economy the subscripts l and v are used to indicate the liquid and vapor phases respectively instead of liq and vap. Hence θ_l and θ_v are the moisture contents in the two phases, and ρ_l and ρ_v are the corresponding densities (ρw and ρ in the previous paper).

The following list contains an explanation of the symbols used and the units in which they are expressed. Numerical values of some constants are also included.

a	volumetric air content, cm^3 of air/cm^3
c_p	specific heat of water vapor at constant pressure, cal g^{-1} °C^{-1}
c_l	specific heat of liquid water, cal g^{-1} °C^{-1}
C	volumetric heat capacity of moist porous medium, cal cm^{-3} °C^{-1}
C_d	volumetric heat capacity of dry porous medium, cal cm^{-3} °C^{-1}
D_{atm}	molecular diffusion coefficient of water vapor in air, cm^2 sec^{-1} ($=4.42 \times 10^{-4}\, T^{2.3}/P$)
D_T	$= D_{Tl} + D_{Tv}$ thermal moisture diffusivity, cm^2 sec^{-1} °C^{-1}
D_{Tl}	$= K\gamma\Psi$ thermal liquid diffusivity, cm^2 sec^{-1} °C^{-1}
D_{Tv}	$= fD_{\mathrm{atm}}\nu\beta h(\nabla T)_a/\rho_l\nabla T$ (with $f = S$ for $\theta_l < \theta_{lk}$, $f = a + a\theta_l/(S - \theta_{lk})$ for $\theta_l > \theta_{lk}$) thermal vapor diffusivity, cm^2 sec^{-1} °C^{-1}
D_θ	$= D_{\theta l} + D_{\theta v}$ isothermal moisture diffusivity, cm^2 sec^{-1}
$D_{\theta l}$	$= K\partial\Psi/\partial\theta_l$ isothermal liquid diffusivity, cm^2 sec^{-1}
$D_{\theta v}$	$= \alpha a D_{\mathrm{atm}}\nu g\rho_v(\partial\Psi/\partial\theta_l)/\rho_l RT$ isothermal vapor diffusivity, cm^2 sec^{-1}
E	rate of evaporation, sec^{-1}
g	acceleration due to gravity, cm sec^{-2} ($=981$)
h	relative humidity
j	mechanical equivalent of heat, erg cal^{-1} ($=4.18 \times 10^7$)

$\mathbf{k}$	unit vector in vertical direction
K	unsaturated hydraulic conductivity, cm sec^{-1}
L	heat of vaporization, cal g^{-1} (=585 at 20°C)
L_0	heat of vaporization at reference temperature T_0, cal g^{-1}
p	partial pressure of water vapor, mm Hg
P	total gas pressure, mm Hg
$\mathbf{q}_h$	heat flux, cal cm^{-2} sec^{-1}
$\mathbf{q}_l$	liquid flux, g cm^{-2} sec^{-1}
$\mathbf{q}_m$	$= \mathbf{q}_l + \mathbf{q}_v$ moisture flux, g cm^{-2} sec^{-1}
$\mathbf{q}_v$	vapor flux, g cm^{-2} sec^{-1}
R	gas constant of water vapor, erg g^{-1} °C^{-1} (=4.615 × 10^6)
S	porosity, cm^3/cm^3
t	time, sec
T	absolute temperature, °K
T_0	arbitrary reference temperature, °K
W	differential heat of wetting, cal g^{-1}
x	horizontal coordinate, cm
z	vertical coordinate, positive upwards, cm
α	tortuosity factor for diffusion of gases in soils (≈0.67)
β	$= d\rho_0/dT$, g cm^{-3} °C^{-1} (=1.05 × 10^{-6} at 20°C)
γ	temperature coefficient of surface tension of water, °C^{-1} (=−2.09 × 10^{-3} at 20°C)
θ	$= \theta_l + \theta_v$ total volumetric moisture content, cm^3/cm^3
θ_l	volumetric liquid content, cm^3/cm^3
θ_{lk}	value of θ_l at which 'liquid continuity' fails
θ_v	volumetric vapor content, cm^3 of precipitable water/cm^3
λ	thermal conductivity, cal cm^{-1} sec^{-1} °C^{-1}
λ_*	hypothetical thermal conductivity of moist porous medium excluding vapor movement, cal cm^{-1} sec^{-1} °C^{-1}
λ_a	thermal conductivity of air, cal cm^{-1} sec^{-1} °C^{-1}
λ_v	apparent thermal conductivity of an air-filled pore due to vapor diffusion, cal cm^{-1} sec^{-1} °C^{-1}
ν	$= P/(P - p)$ mass flow factor
ρ_v	density of water vapor, g cm^{-3}
ρ_0	density of saturated water vapor, g cm^{-3}
ρ_l	density of liquid water, g cm^{-3}
Ψ	water pressure, with atmospheric pressure as datum, cm
$(\nabla T)_a$	average temperature gradient in air-filled pores, °C cm^{-1}

THE EQUATIONS FOR HEAT AND MOISTURE TRANSFER

Moisture transfer—The equations for the liquid and vapor flux densities as given by *Philip* and *de Vries* [1957] are

$$\mathbf{q}_l/\rho_l = -D_{\theta l}\nabla\theta_l - D_{Tl}\nabla T - K\mathbf{k} \tag{1}$$

$$\mathbf{q}_v/\rho_l = -D_{\theta v}\nabla\theta_l - D_{Tv}\nabla T \tag{2}$$

Combination of these equations leads to the total moisture flux density

$$\mathbf{q}_m/\rho_l = -D_\theta\nabla\theta_l - D_T\nabla T - K\mathbf{k} \tag{3}$$

By application of the continuity principle the following differential equations for θ_l, θ_v and θ are obtained

$$\frac{\partial\theta_l}{\partial t} = -\nabla(\mathbf{q}_l/\rho_l) - E = \nabla(D_{\theta l}\nabla\theta_l) + \nabla(D_{Tl}\nabla T) + \frac{\partial K}{\partial z} - E \tag{4}$$

$$\frac{\partial\theta_v}{\partial t} = -\nabla(\mathbf{q}_v/\rho_l) + E = \nabla(D_{\theta v}\nabla\theta_l) + \nabla(D_{Tv}\nabla T) + E \tag{5}$$

$$\frac{\partial\theta}{\partial t} = -\nabla(\mathbf{q}_m/\rho_l) = \nabla(D_\theta\nabla\theta_l) + \nabla(D_T\nabla T) + \frac{\partial K}{\partial z} \tag{6}$$

Eq. (1), (2), (3), and (6) are identical with (12), (7), (20), and (23) respectively of the paper cited with the exception that in the latter no distinction between θ and θ_l was made. The possibility of water transfer from the liquid to the vapor phase is recognized by the introduction of an 'evaporation' term, $\pm E$, on the right hand sides of (4) and (5). In the case of condensation E is negative, of course.

Assuming that at every instant liquid water is in equilibrium with water vapor the following relation between θ_v and θ_l holds

$$\theta_v = (S - \theta_l)\rho_v/\rho_l = (S - \theta_l)\rho_0 h/\rho_l \tag{7}$$

Hence

$$\frac{\partial\theta_v}{\partial t} = \left[\frac{(S-\theta_l)\rho_0 gh}{\rho_l RT}\frac{\partial\Psi}{\partial\theta_l} - \frac{\rho_v}{\rho_l}\right]\frac{\partial\theta_l}{\partial t} + \frac{(S-\theta_l)h\beta}{\rho_l}\frac{\partial T}{\partial t}$$

$$= \left[\frac{D_{\theta v}}{\alpha v D_{\text{atm}}} - \frac{\rho_v}{\rho_l}\right]\frac{\partial\theta_l}{\partial t} + \frac{(S-\theta_l)h\beta}{\rho_l}\frac{\partial T}{\partial t} \qquad (8)$$

On the right hand side of (8) a term with $\partial h/\partial T$ has been neglected. Philip and de Vries argued that this term is negligible in comparison with the second term on the right hand side of (8).

The value of E follows immediately from (5) and (8). Substitution in (4) leads to the following equation in θ_l and T

$$\left(1 + \frac{D_{\theta v}}{\alpha v D_{\text{atm}}} - \frac{\rho_v}{\rho_l}\right)\frac{\partial\theta_l}{\partial t} + \frac{(S-\theta_l)h\beta}{\rho_l}\frac{\partial T}{\partial t} = \nabla(D_\theta\nabla\theta_l) + \nabla(D_T\nabla T) + \frac{\partial K}{\partial z} \qquad (9)$$

Heat transfer—The heat flux density will be tentatively expressed as follows

$$\mathbf{q}_h = -\lambda_*\nabla T + L_0\mathbf{q}_v + c_p(T - T_0)\mathbf{q}_v + c_l(T - T_0)\mathbf{q}_l \qquad (10)$$

The first term on the right hand side represents the contribution of pure heat conduction; λ_* is the thermal conductivity of the porous medium in the hypothetical case where no moisture movement occurs. The second term represents the transfer of latent heat by vapor movement. The third and fourth terms represent the transfer of sensible heat in vapor and liquid form respectively. T_0 is an arbitrary reference temperature, L_0 is the heat of vaporization at T_0. The tentative character of (10) arises from the fact that the various terms on its right hand side have been considered as additive, which is strictly not permissible as will be discussed below. Further it has been assumed that heat transfer by convection and radiation is negligible, which is usually the case [*de Vries*, 1952a].

The total heat content per unit of volume is

$$C_d(T - T_0) + L_0\rho_l\theta_v + c_p\rho_l\theta_v(T - T_0) + c_l\rho_l\theta_l(T - T_0) - \rho_l\int_0^{\theta_l} W\,d\theta_l \qquad (11)$$

where C_d is the volumetric heat capacity of the dry medium and W the differential heat of wetting. According to thermodynamic theory [*Edlefsen* and *Anderson*, 1943]

$$jW = RT^2\partial\ln h/\partial T = -g(\Psi - T\partial\Psi/\partial T) \qquad (12)$$

Applying the principle of heat conservation we have

$$C\frac{\partial T}{\partial t} + L_0\rho_l\frac{\partial\theta_v}{\partial t} + c_p\rho_l(T - T_0)\frac{\partial\theta_v}{\partial t} + c_l\rho_l(T - T_0)\frac{\partial\theta_l}{\partial t} - \rho_l W\frac{\partial\theta_l}{\partial t} = -\nabla\mathbf{q}_h$$

$$= \nabla(\lambda_*\nabla T) - L_0\nabla\mathbf{q}_v - c_p(\mathbf{q}_v\nabla T) - c_l(\mathbf{q}_l\nabla T) - c_p(T - T_0)\nabla\mathbf{q}_v - c_l(T - T_0)\nabla\mathbf{q}_l \qquad (13)$$

Using (4), (5) and the relation

$$L(T) = L_0 - (c_l - c_p)(T - T_0) \qquad (14)$$

this reduces to

$$C\frac{\partial T}{\partial t} - \rho_l W\frac{\partial\theta_l}{\partial t} = \nabla(\lambda_*\nabla T) - L\rho_l E - c_p(\mathbf{q}_v\nabla T) - c_l(\mathbf{q}_l\nabla T) \qquad (15)$$

where the reference temperature no longer occurs.

Combining (1), (2), (4), (5), (8), (12) and (15) we obtain

$$[C + L(S - \theta_l)h\beta]\frac{\partial T}{\partial t} + \left[\frac{L\rho_l D_{\theta v}}{\alpha v D_{\text{atm}}} - L\rho_v + \rho_l j^{-1}g\left(\Psi - T\frac{\partial\Psi}{\partial T}\right)\right]\frac{\partial\theta_l}{\partial t}$$

$$= \nabla[(\lambda_* + L\rho_l D_{Tv})\nabla T] + L\rho_l\nabla(D_{\theta v}\nabla\theta_l) + \rho_l c_p[(D_{\theta v}\nabla\theta_l + D_{Tv}\nabla T)\nabla T] + \rho_l c_l[(D_{\theta l}\nabla\theta_l + D_{Tl}\nabla T + K\mathbf{k})\nabla T] \qquad (16)$$

The third term on the right hand side of (16), representing sensible heat transfer by vapor movement, is usually negligible.

In the present treatment it has been tacitly assumed that all processes of heat transfer take place uniformly throughout the porous medium, and that sources and sinks of heat (arising from evaporation-condensation and wetting-drying) are distributed uniformly as well. The former assumption is already implicit in the additive structure of the right hand side of (10). However, in reality vapor transfer takes place only in the air-filled pore space, liquid movement only in the water-filled pore space, while evaporation and condensation occur at the water-air interfaces. A complete analytical treatment of these processes would lead us to a 'microscopic' study of heat and moisture transfer in porous media. In such a complete theory the pore geometry has to be specified and proper boundary conditions must be introduced at all the solid-liquid and liquid-gas interfaces. Such

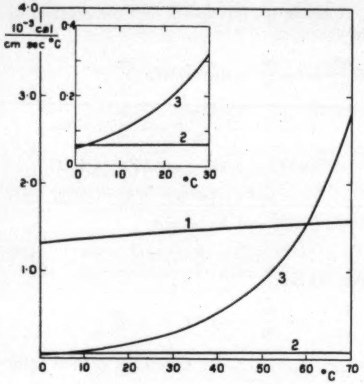

FIG. 1 – Thermal conductivities of water (curve 1) and air (curve 2) and values of $\nu\beta LD_{\mathrm{atm}}$ (curve 3) in relation to temperature; the inset has an enlarged scale of ordinates

an analysis will be extremely difficult and it will not be attempted here.

An exception will be made for vapor distillation due to temperature gradients in the air-filled pores. *Krischer* and *Rohnalter* [1940] have shown that this leads to an apparent increase in the thermal conductivity of the air-filled pores. This theory was incorporated by *de Vries* [1952ab] in a theoretical method for calculating the thermal conductivity of porous media. In this method the conductivity of the air-filled pores is expressed as

$$\lambda_a + \lambda_v = \lambda_a + h\nu\beta LD_{\mathrm{atm}} \tag{17}$$

and the usual boundary conditions of continuity of temperature and (apparent) heat flux at the interfaces are used. Numerical values of $\nu\beta LD_{\mathrm{atm}}$ are given in Figure 1 together with values of the thermal conductivities of water and air. Experimental evidence in support of this theory has also been given by *Krischer* and *Rohnalter* [1940] and *de Vries* [1952ab].

As an alternative to the tentative formulation given above we can therefore replace the expression $\lambda_* + L\rho_l D_{Tv}$ in the first term on the right hand side of (16) by λ, this being the apparent conductivity of the medium including the effect of vapor distillation due to temperature gradients. (It will be noted that $\lambda \neq \lambda_* + L\rho_l D_{Tv}$, because the heat fluxes in different parts of the medium are not additive). This leads to the following revised forms of Eqs. (10) and (16)

$$\mathbf{q}_h = -(\lambda - L\rho_l D_{Tv})\nabla T + L\mathbf{q}_v + c_l(T - T_0)\mathbf{q}_m \tag{18}$$

and (with the omission of the term with c_p)

$$[C + L(S - \theta_l)h\beta]\frac{\partial T}{\partial t} + \left[\frac{L\rho_l D_{\theta v}}{\alpha\nu D_{\mathrm{atm}}} - L\rho_v + \rho_l j^{-1}g\left(\Psi - T\frac{\partial\Psi}{\partial T}\right)\right]\frac{\partial\theta_l}{\partial t}$$
$$= \nabla(\lambda\nabla T) + L\rho_l\nabla(D_{\theta v}\nabla\theta_l) + \rho_l c_l \cdot[(D_{\theta l}\nabla\theta_l + D_{Tl}\nabla T + K\mathbf{k})\nabla T] \tag{19}$$

In (18) use has been made of (14) to eliminate L_0, this can of course be done in either formulation.

It might appear arbitrary to single out the particular term arising from vapor distillation due to temperature gradients. However, this term often represents the most important contribution of moisture movement to the heat transfer. Since it increases the conductivity of the poorest conducting part of the system (namely, the gaseous part) it contributes markedly to the overall conductivity of the porous medium. From (17) and Figure 1 it follows, for instance, that in the temperature range of 0° to 40°C the conductivity of the air-filled pores can be increased by a factor 2 to 9 by the vapor contribution.

The second term on the right hand side of (19) also arises from vapor diffusion, this time under the influence of moisture gradients. Since the corresponding heat flux is not proportional to ∇T it cannot be incorporated in λ in the same way as the term $\nabla(L\rho_l D_{Tv}\nabla T)$.

For the present we shall consider (10) with (16), and (18) with (19) as equivalent alternatives. We shall discuss the applicability of each of these alternatives further in the following section.

Eq. (9) and (16) or (19) govern the simultaneous transfer of moisture and heat in porous media. Eq. (16) or (19) replaces the Fourier equation of heat conduction. They are more general than (24) in the paper of Philip and de Vries; (19) reduces to the latter when heat transfer by liquid movement is negligible and $W = \partial\theta_v/\partial t = 0$. The generation of heat due to viscosity of the moving liquid has been neglected in the present treatment. It would give rise to an additional term $gq_l^2/j\rho_l K$ on the right hand sides of (16) and (19). This term is negligible under most circumstances. Eq. (9) is more general than (23) in the previous paper. Note that the coefficients occurring in these equations are functions of the dependent variables, θ_l and T. They all depend strongly on θ_l. Their variation with T is less outspoken except for $D_{\theta v}$ and D_{Tv} which both increase rapidly with increasing temperature.

For the sake of completeness we must point out that the present theory cannot be applied in cases where hysteresis operates [*Philip*, 1955].

Numerical values of the various diffusivities occurring in these equations can be calculated once Ψ and K are known as functions of θ_l. The thermal properties (λ and C) of a soil can be calculated from its composition as discussed by the author [*de Vries*, 1952ab].

Values of the diffusivities for Yolo light clay (a clay loam) were published by *Philip* [1955, 1957c] and *Philip* and *de Vries* [1957]. These are based on measurements of Ψ and K by *Moore* [1939]. *Philip* [1955] extrapolated the Ψ and K curves at the low end of the moisture range. The thermal conductivity of this soil in relation to θ_l, as calculated by the author, was also published by *Philip* [1957c]. Its heat capacity is: $C = 0.23 + \theta_l$.

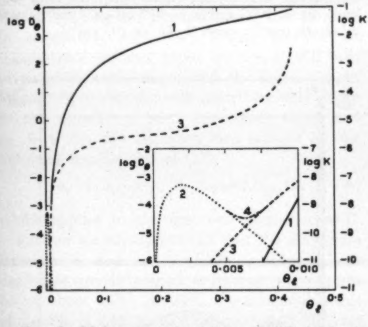

FIG. 2 – Moisture conductivity and diffusivities in relation to moisture content θ_l for a medium sand at 20°C; curve 1, K(cm sec^{-1}); curve 2, $D_{\theta v}$ (cm^2 sec^{-1}); curve 3, $D_{\theta l}$ (cm^2 sec^{-1}); curve 4, $D_\theta = D_{\theta v} + D_{\theta l}$

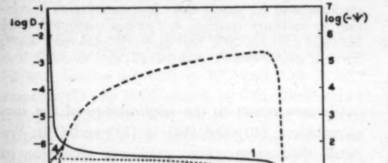

FIG. 3 – Water pressure and thermal moisture diffusivities in relation to moisture content, θ_l, for a medium sand at 20°C; curve 1, Ψ (cm); curve 2, D_{Tv} (cm^2 sec^{-1} °C^{-1}); curve 3, D_{Tl} (cm^2 sec^{-1} °C^{-1}); curve 4, $D_T = D_{Tv} + D_{Tl}$

Since the numerical values will be used only for illustrative purposes we are here not so much concerned with the exact values of the various quantities as with their order of magnitude and in the way they change with θ_l and T.

To illustrate the influence of soil texture values for a sand (particle sizes 0.01 to 0.06 cm) are given in Figures 2 and 3. Values of λ and Ψ in relation to θ_l for this sand were determined by the author [*de Vries*, 1952a]. Its heat capacity, $C = 0.27 + \theta_l$. Values of K were calculated from the $\Psi(\theta_l)$ curve by the method of *Childs* and *Collis-George* [1950]. The calculations were formally extended to θ_l-values as low as 0.006, although it is very doubtful whether the procedure is still applicable at such low moisture contents. This was necessary because the results indicate that moisture movement in the liquid and the vapor phase are of the same order of magnitude in the moisture range $0.006 < \theta_l < 0.02$ (assuming the order of magnitude of the calculated K values to be correct). The value 0.10 was chosen for θ_{lK}. All numerical values given here are for 20°C.

It follows from the equations that true equilibrium in the soil requires that both the total potential ($= \Psi + z$; the influence of soluble salts is left out of consideration here) and the temperature are constant. In a non-equilibrium state there will always be interaction between heat and moisture transfer, even if initially the temperature gradient were zero.

It can be easily checked that for such processes as infiltration of water available in excess at the soil surface and water movement leading to evaporation from bare soil at rates of the order of 10^{-6} g cm^{-2} sec^{-1} or more the dominant term on the left hand side of (9) is $\partial\theta_l/\partial t$, while the term $\nabla(D_T \nabla T)$ on the right hand side is small in comparison with the other terms. These processes can therefore be regarded as isothermal to a good degree of approximation [*Philip*, 1957ab]. When q_m is of the order of 10^{-7} g cm^{-2} sec^{-1} or less moisture movement due to temperature gradients is no longer negligible [*Philip*, 1957c; *de Vries*, 1957].

Similarly in soils under natural conditions the dominant terms in (19) are often $C\partial T/\partial t$ and $\nabla(\lambda \nabla T)$.

As an application of the present theory we shall discuss steady state heat conduction in a moist soil in greater detail in the following section.

STEADY STATE HEAT CONDUCTION

We shall assume that an experiment in heat conduction is carried out in which both θ_l and T vary either in a horizontal direction or in a vertical direction and that a steady state has been reached ($\partial\theta_l/\partial t = \partial T/\partial t = 0$). The steady state will be characterized by the magnitudes of the moisture flux q_m and the heat flux q_h in the sample.

The moisture and the temperature gradient can be solved from (2), (3) and (18). For the 'vertical' case we find

$$\frac{d\theta_l}{dz} = \frac{q_h D_T - K\lambda - q_m c_l (T - T_0) D_T - q_m \lambda/\rho_l}{\lambda D_\theta - L\rho_l D_{\theta v} D_T} \tag{20}$$

$$\frac{dT}{dz} = -\frac{q_h D_\theta - K L \rho_l D_{\theta v} - q_m c_l (T - T_0) D_\theta - q_m L D_{\theta v}}{\lambda D_\theta - L\rho_l D_{\theta v} D_T} \tag{21}$$

Similar equations for the 'horizontal' case are obtained by substituting x for z and 0 for K. In the alternative formulation (starting from (10) instead of (18)) we must substitute $\lambda_* + L\rho_l D_{Tv}$ for λ.

In thermal conductivity experiments the soil sample is usually bounded by solid surfaces [for example, *Kersten*, 1948] and in this case $q_m = 0$ in the steady state. For the horizontal case (20) and (21) then reduce to

$$\frac{d\theta_l}{dx} = \frac{q_h D_T}{\lambda D_\theta - L\rho_l D_{\theta v} D_T} \tag{22}$$

$$\frac{dT}{dx} = -\frac{q_h D_\theta}{\lambda D_\theta - L\rho_l D_{\theta v} D_T} \tag{23}$$

The apparent thermal conductivity found in an experiment of this type is therefore $\lambda - L\rho_l D_{\theta v} D_T/D_\theta$, or $\lambda_* + L\rho_l(D_{Tv} D_{\theta l} - D_{\theta v} D_{Tl})/D_\theta$ in the alternative formulation.

Values of $d\theta_l/dx$ and dT/dx calculated from (22) and (23) for Yolo light clay and the sand of Figures 2 and 3 are given in Figures 4 and 5. They hold for 20°C and $q_h = 10^{-3}$ cal cm^{-2} sec^{-1}. It will be seen that the moisture gradient in the sample is very small, except in the θ_l region where D_T is not small in comparison with D_θ. This region is narrower and at a lower average moisture content for the coarser textured soil than for the soil of finer texture. Values of $\theta_l(x)$ and $T(x)$ can be obtained by numerical integration of (22) and (23) for given boundary conditions.

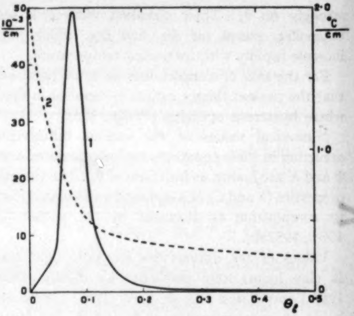

FIG. 4 – Moisture and temperature gradients in Yolo light clay for steady state heat conduction in relation to moisture content, θ_l; values computed from (22) and (23) for 20°C and $q_h = 10^{-3}$ cal cm^{-2} sec^{-1}; curve 1, $d\theta_l/dx$ (cm^{-1}); curve 2, dT/dx (°C cm^{-1})

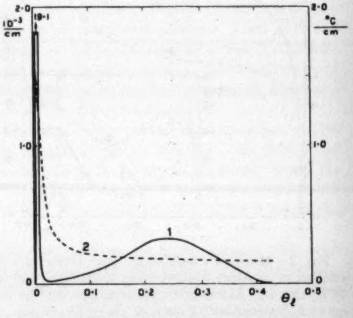

FIG. 5 – Moisture and temperature gradients in a medium sand for steady state heat conduction in relation to moisture content, θ_l; values computed from (22) and (23) for 20°C and $q_h = 10^{-3}$ cal cm^{-2} sec^{-1}; curve 1, $d\theta_l/dx$ (cm^{-1}), curve 2, dT/dx (°C cm^{-1})

We now revert to the applicability of the two alternatives, (10) and (16) or (18) and (19). We recall that temperature gradients give rise to moisture movement in the vapor and the liquid phase of which the former contributes most to the heat transfer. In steady state experiments with $q_m = 0$ there will be a return moisture flow of equal magnitude due to moisture gradients. We now distinguish the following three θ_l regions.

The region where $D_{\theta l} \gg D_{\theta v}$.—In this case the return flow is almost entirely in the liquid phase. Vapor diffusion due to temperature gradients will contribute fully to the heat transfer and equation (18) must be preferred. It will be noted that in this region $L\rho_l D_{\theta v} D_T / D_\theta \ll \lambda$, so that the apparent conductivity measured in an experiment of this type is the same as that predicted by the theory based on (17).

The region where $D_{\theta l} \ll D_{\theta v}$—Here moisture movement is almost exclusively in the vapor phase, as it can be easily checked that D_{Tl} is also small in comparison with D_{Tv} in this region. There will be no net vapor movement and (10) must therefore be used. Eq. (22) and (23) now reduce to

$$d\theta_l/dx = q_h D_{Tv}/\lambda_* D_{\theta v} \qquad (24)$$

$$dT/dx = -q_h/\lambda_* . \qquad (25)$$

The region where $D_{\theta l}$ and $D_{\theta v}$ have comparable magnitudes—In this region D_{Tl} will still be small in comparison with D_{Tv}. Return flow to the temperature induced vapor movement will take place both in the vapor and the liquid phases. Hence, vapor diffusion will contribute only partly to the transfer of heat. For steady states and $q_m = 0$ this can be taken into account by the following modification of (17)

$$\lambda_a + \lambda_v = \lambda_a + D_{\theta l} h \nu \beta L D_{atm}/D_\theta \qquad (26)$$

which applies to the first two regions as well.

Further we must point out that the differences between λ and $\lambda_* + L\rho_l D_{Tv}$, although not negligible, are fairly small, at least at temperatures below about 30°C. At 20°C the maximum value of $L\rho_l D_{Tv}$ is 0.15×10^{-3} cal cm^{-1} sec^{-1} °C^{-1} for both the sand and Yolo light clay. This is small in comparison with λ (or λ_*) except at low moisture contents. The difference between λ and λ_* is generally of the same order of magnitude as $L\rho_l D_{Tv}$. For instance, for the sand at 20°C and $\theta_l = 0.09$ the (calculated and measured) value of λ is 4.38×10^{-3}, while the (calculated) values of λ_* and $L\rho_l D_{Tv}$ are 4.06×10^{-3} and 0.14×10^{-3} respectively. At 20°C and $\theta_l = 0.01$ these values are: $\lambda = 0.90 \times 10^{-3}$, $\lambda_* = 0.64 \times 10^{-3}$ and $L\rho_l D_{Tv} = 0.15 \times 10^{-3}$. However, $L\rho_l D_{Tv}$ increases rapidly with increasing temperature and at 60°C, for instance, its maximum value is about 1.0×10^{-3} cal cm^{-1} sec^{-1} °C^{-1}.

The situation is more complicated for steady state conditions in the 'vertical' case or when $\mathbf{q}_m$ is not zero. Then $\mathbf{q}_h$ is no longer strictly proportional to ∇T. The outcome of a thermal conductivity experiment, for instance, will depend on the boundary conditions for moisture flow and on the direction of the temperature gradient. However, K is practically zero in the second region and there is no difference between transfer of heat and moisture in horizontal and vertical directions in this region.

Under non-stationary conditions (16) or (19) must be used with proper initial and boundary conditions. Here also $\mathbf{q}_h$ will not be proportional to ∇T. An analysis of non-stationary experiments for determining the thermal conductivity using cylindrical probes will be published elsewhere (*de Vries* and *Peck* [1958ab]).

Under most circumstances it will be best to apply (18) and (19) in the first region. For the second and third regions the choice between the alternative formulations must be decided upon by a careful consideration of the experimental conditions. If, for instance, water is supplied at a sufficient rate, while $\mathbf{q}_m$ and $\mathbf{q}_h$ are in the same direction (18) and (19) can be applied over the entire range of moisture contents.

Calculation of Total and Component Potentials of Water in Soil*

G. H. BOLT AND R. D. MILLER

Abstract—The total potential of water in moist soil is assumed to be the sum of gravitational, pressure, osmotic and adsorption components. Osmotic potential is related to solute concentration at any point. Adsorption potential is assumed to depend on interaction of water dipoles with electric fields associated with the solid-liquid interface. The Gouy-Chapman theory of the electric double layer provides a basis for computing both osmotic and adsorption potentials at any point in the liquid outside the first few monolayers of water enveloping soil particles. From these, pressure potential can be calculated. Curves illustrating the variation of component potentials with distance from a particle are presented along with curves relating total potential to film thickness for soils brought to hydraulic equilibrium or to vapor equilibrium with external solutions. Measurement of total potential by freezing point depression is questioned.

INTRODUCTION

It was logical that *Buckingham's* [1907] original concept of the capillary potential of soil moisture would be extended to include not only the pressure and gravitational components, but also the effects of solutes and force fields other than gravity. *Edlefsen* (then Chairman of the Committee on Soil Moisture, AGU) and *Anderson* [1943], in their monumental *Thermodynamics of soil moisture*, considered these effects in detail, introducing the concepts of the total specific free energy (equivalent to total potential) of soil moisture, and its components due to pressure, solutes, and force fields. The force field was regarded as the sum of the gravitational field and any other body-force fields present.

Edlefsen and Anderson did not attempt to specify the force field emanating from an individual soil grain but presumed that it behaved in more or less the same fashion as the gravitational field of the Earth, that is, a field that declines monotonically with distance, reaching its zero value at infinite distance. They pointed out that the variation of this field with distance from the soil grain was "... assumed by various investigators to obey anything from the inverse square law to an inverse fifth law...." They also observed that the force field was probably electrical. Lacking a description of the force field, they could only include its effects in their equations in a purely formal manner, placing a severe limitation upon their other achievements.

An entirely new approach was introduced by *Schofield* [1946] who, using the Gouy-Chapman theory of the electric double layer, calculated a relationship between the thickness of a water film on a charged surface and the osmotic pressure at the film surface. Assuming, as Schofield did, that at this film surface only the osmotic potential and the pressure potential differ from their standard values, one can calculate the pressure at the film surface as a function of the film thickness. Using some experimental data from literature sources, Schofield showed that good agreement was found for water films on mica, although apparently poor agreement was found for dilute solutions of NaCl on lead glass. More recent experiments with silicate clay minerals [*Bolt* and *Miller*, 1955; *Bolt*, 1956; *Warkentin* and others, 1957] provide instances of remarkable agreement between theory and experiment, indicating that, in principle, the assumption that the adsorption potential vanishes at the film surface is correct in selected cases. A closer examination of the nature of the adsorption potential shows indeed that, excepting the first few layers of water molecules adsorbed on the surface, the adsorption forces are proportional to the square of the electric-field intensity. These forces thus become equal to zero both at the film surface and, in regions where no phase boundary between water and air occurs, at some location between opposing solid-liquid interfaces. In their treatment of adsorptive force fields, Edlefsen and Anderson did not anticipate this critical consequence of the application of the double-layer theory and, as a result, the need for much of the more complicated and unrewarding part of their analysis disappears.

This paper presents a recombination of Buckingham's capillary potential concept and the thermodynamic analysis of Edlefsen and Anderson with Schofield's application of the theory of the electric double layer to soil water systems, together with numerical results for some appropriate systems.

THE TOTAL SOIL MOISTURE POTENTIAL

Thermodynamic and mechanical analyses of the energetics of water in soil give results which are identical except in form. *Edlefsen* and *Anderson* [1943] and recently, *Low* and *Deming* [1953] use thermodynamic variables for their analyses. We elect to use the notation and terminology of mechanics.

The total potential is defined as the minimum energy per gram of water which must be expended in order to transport an infinitesimal test body of water from a specified reference state to any point within the liquid phase of a soil-water system which is in a state of rest. The reference state is commonly taken to be a pool of pure water at the same temperature with a flat surface exposed to atmospheric pressure at a known elevation. Under conditions in which the soil will spontaneously adsorb water from the reference state, the potential is a negative quantity. In any soil-water system in a state of rest, the total potential does not vary from point to point in the system.

The total potential Ψ depends upon the force fields which act upon the test body of water as the transfer is made. These forces are presumed to be: gravity, the pressure-gradient force, the diffusion or osmotic-pressure gradient force, and an electrical 'adsorption' force. If the force per gram mass of water is represented by the vector $\mathbf{F}$, the work done against these forces is

$$\Psi = -\int \mathbf{F}_g \cdot d\mathbf{l} - \int \mathbf{F}_p \cdot d\mathbf{l} - \int \mathbf{F}_{0p} \cdot d\mathbf{l} - \int \mathbf{F}_a \cdot d\mathbf{l} \quad (1)$$

where $d\mathbf{l}$ is an infinitesimal displacement vector along the path taken by the test body. The respective integrals will be represented by the symbols ζ, φ, ω, and α and will be called the gravitational potential, the pressure potential, the osmotic potential, and the adsorption potential, respectively. In some instances centrifugal-force fields may be involved and an additional term may be added. Temperature gradients, if present, introduce special problems which will not be considered in this treatment.

The gravitational potential—The force per gram of water exerted by the Earth's gravitational field is the vector

$$\mathbf{F}_g = -g\mathbf{k} \quad (2)$$

where $\mathbf{k}$ is a unit vector in the z direction, positive upwards. The negative sign indicates that the gravitational force acts in the opposite (downward) direction. The strength of the gravitation field is the scalar g.

Thus

$$\zeta = g\int \mathbf{k} \cdot d\mathbf{l} = g\int dz \quad (3)$$

The pressure potential—The force per gram acting on water in a pressure field is the vector

$$\mathbf{F}_p = -v\nabla p \quad (4)$$

where v is the specific volume (reciprocal density) of the water. The minus sign indicates that the force acts in a direction of decreasing pressure. Thus

$$\varphi = \int \nabla p \cdot d\mathbf{l} = v\int dp \quad (5)$$

The osmotic potential—When two solutions of unequal concentration are in communication via a semipermeable membrane, the effects of the diffusion force are apparent. If the volumes of both phases are held constant, the pressure will increase in the more concentrated solution until it exceeds the pressure in the less concentrated solution by an amount equal to the difference in the osmotic pressures of the two solutions. If the membrane is visualized as possessing a concentration gradient, then it is apparent that, at equilibrium, the pressure gradient force on water in the membrane just balances the osmotic pressure gradient force (or diffusion force). In the following discussion it will be assumed that the increment of osmotic pressure of the solutions is independent of pressure. It follows that

$$\mathbf{F}_{0p} = v\nabla\Pi \quad (6)$$

where Π is the osmotic pressure. The positive sign indicates that the force acts in the direction in which Π increases. Thus

$$\omega = -v\int \nabla\Pi \cdot d\mathbf{l} = -v\int d\Pi \quad (7)$$

The adsorption potential—Attractive (adsorptive) forces between solids and water can be divided in two categories, short-range forces and long-range forces. To the first category belong chemical forces (caused by localized interactions between the electron clouds of surface atoms and water molecules) and London-van der Waals' forces which are due to the interaction of transient electric fields arising from the relative motion of the atom nuclei and their electron clouds. The latter forces, although not as localized as the chemical forces, are in the case of interaction between water and a solid surface still of short range as a result of the destructive interference with fields from other atoms as the distance between the atoms under consideration increases. Although such forces account for the cohesive strength of the water and the phenomenon of surface tension, it seems unlikely that the effective range with regard to the adsorption of water on solid surfaces extends beyond the first few molecular layers adjacent to the interface.

In contrast to these short-range forces, the long-range forces, which are due to the interaction of the water dipoles with the electrostatic field emanating from a charged solid surface, may easily extend beyond 100 A. It seems reasonable, therefore, to ignore the effects of the short-range forces in the soil-water systems, except at low water contents usually encountered only in the laboratory.

The interaction between a polar or polarizable medium and electrostatic field is discussed extensively in textbooks [*Harnwell*, 1938]. A nonuniform field exerts a net translational force on a dipole as a result of the difference in field intensity at the two poles of the dipole. The magnitude of this force depends upon (1) the degree of polarization of the water, which, if the field is not too intense (to avoid dielectric saturation), is simply proportional to the field intensity, and (2) the space rate of change of the field intensity. According to standard text books, the energy of a polar medium associated with this force is equal to

$$\alpha = -\frac{\epsilon - 1}{8\pi} v \int d(\nabla\psi)^2 \qquad (8)$$

where ϵ is the dielectric constant (assumed to be independent of the field intensity, see *Bolt* [1955]) and ψ is the electric potential.

Notice that the adsorption energy is always a negative energy if the field intensity differs from zero and the dielectric constant exceeds unity. The magnitude of the field intensity at certain locations in a soil-water system may be approximated with the aid of the Gouy-Chapman theory of the electric double layer.

THE ELECTRIC DOUBLE LAYER

Details of the Gouy-Chapman theory mentioned above have been presented by *Schofield* [1946], *Verwey* and *Overbeek* [1948], *Bolt* [1955], and others. In effect, this theory assumes that when a segregation of charge occurs at a solid-liquid interface, the ions present in the liquid phase are acted on (1) by a diffusion force which tends to scatter all solute species uniformly throughout the solution, and (2) by Coulombic forces which tend to distribute the ions in a manner which will minimize the electric potential differences occurring in the system or, in effect, minimize the segregation of charges.

Equating these forces, one may write

$$-v\nabla\Pi = v\rho\nabla\psi \qquad (9)$$

where ρ is the net electrical charge per unit volume. The minus sign before the left hand term indicates that the diffusion force on the ions present in the double layer acts in the direction in which Π decreases. Observe that when the net charge density ρ is positive, the net Coulombic force on the ion acts in the direction in which ψ decreases, and vice versa.

Introducing the Poisson equation ($\nabla^2\psi = -4\pi\rho/\epsilon$), one obtains

$$\nabla\Pi = \frac{\epsilon}{4\pi}\nabla\psi\nabla^2\psi \qquad (10)$$

This equation cannot be solved in its general form; in the special case of a one-dimensional electric field one finds for arbitrary points m and n

$$\Pi_m = \Pi_n + \frac{\epsilon}{8\pi}[(d\psi/dx)_m^2 - (d\psi/dx)_n^2] \qquad (11)$$

or, if the location n is defined as the point where $(d\psi/dx)$ equals zero

$$(d\psi/dx)_m = \sqrt{\frac{8\pi}{\epsilon}(\Pi_m - \Pi_n)} \qquad (12)$$

This equation may be regarded as the starting equation of the Gouy-Chapman theory of the planar double layer. To complete this theory it is assumed that the double layer ions exhibit ideal behavior (that is, $\Pi = RT\Sigma c$, in which Σc is the combined concentration of all ionic species). It should be emphasized that the Gouy-Chapman theory ignores the detailed structure double layer, for the charges present are finite and the electric field is not truly one-dimensional.

For the spherical symmetrical case, numerical

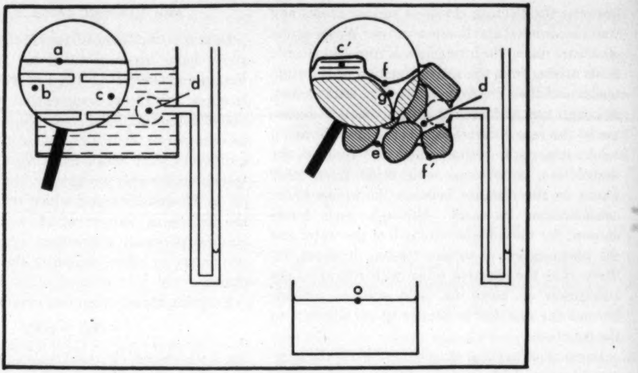

FIG. 1 – Schematic representations of ideal clay-water system (left) and mixed system (right) with points mentioned in the text identified by letter

solutions of (10) can be found in the literature [*Hoskin*, 1953]. In practice, the solution obtained from the planar case becomes acceptable if $\kappa r > 10$, in which r is the radius of curvature of the charged surface; κ is Debye's ionic parameter. This implies that in most soils the planar solution is satisfactory for $r > 1000$ A; in other words, the double layer adjacent to all soil mineral surfaces can be approximated quite well with the planar solution, with the exception of the regions very close to the edges of plate-shaped clay particles. This observation is of importance, for it will be argued that the majority of the moisture present in soils can probably be regarded as moisture present in either planar double layers or in field-free regions in the large interstices.

RELATIONSHIP OF COARSE TO FINE GRAINED SYSTEMS

Classical ideas of water in porous media as exemplified by *Haines'* [1930] analysis assume that all soil grains are supported in place by contact with adjacent grains and that the pore geometry is more or less fixed. When one is given the pore geometry and the surface-tension equation, in principle one can work out all possible configurations of the air-water interface, which are consistent with an arbitrarily chosen pressure in the liquid phase, taking into account the hydrostatic variation of pressure with elevation. An analysis of this type usually acknowledges the presence of an adsorbed film of water on solid surfaces which would otherwise be in direct contact with air.

In contrast to the familiar case described is the ideal clay-water system in which the particles are not in direct contact but are separated by layers of water. Removal of water from such a system does not introduce a third phase but merely causes the particles to move closer to one another with the pores remaining water saturated.

Although both cases may be found in nature, a majority of soils probably represent a mixture of these two extremes with a more or less rigid framework of coarse particles corresponding to the first system described but containing space occupied by systems resembling the latter.

Figure 1 has been drawn to illustrate the essential features of ideal clay, coarse-grained, and mixed systems. In the following sections the component potentials at the various points identified in the figure will be analyzed.

IDEAL CLAY-WATER SYSTEMS

Although particles of clay size occur in a variety of shapes, the common silicate clays evidently possess regular faces which are either planar or a series of planes arranged in terraces. In the lattices of the 2:1 type the particles exist as thin sheets which are usually oriented in a more or less parallel array. For the purposes of this paper an ideal clay-water system will be one in which the particles approximate infinite sheets of uniform thickness in equally spaced, parallel array with interacting double layers which render this the stable configuration. It will also be assumed that the quantity of material present is sufficiently large that the curvature of the air-water interface which bounds the system is negligible. The diagram on the left in Figure 1 is intended to represent such a system. Beginning with the reference pool and considering the points indicated, one finds the following values of the component potentials.

Point o—This point is just inside the liquid phase at the flat surface of the reference pool of pure water. By convention

$$\Psi_0 = z_0 = p_0 = \Pi_0 = \psi_0 = (\nabla\psi)_0 = (\nabla^2\psi)_0 \equiv 0 \quad (13)$$

Point d—This point is found in the 'equilibrium dialyzate' of the soil-water system. This is the liquid which would be found in a tensiometer cup equilibrated with the soil, or which would be obtained by compressing the soil and allowing a small quantity of water to escape at atmospheric pressure through a membrane permeable to water and salts. The gage pressure required to initiate discharge is $-p_d$ where p_d is the normal gage pressure (usually negative) of the equilibrium dialyzate present in a tensiometer cup inserted in the soil. Moreover the 'swelling pressure' which this system can exert on its surroundings when given access to equilibrium dialyzate at atmospheric pressure will be $-p_d$. For an unsaturated system, the 'surroundings' of the soil-water system will be the gas phase.

Formation of bubbles of air and water vapor in a tensiometer cup as p_d decreases limits its useful range to gage pressures greater than about -0.85 atmosphere [*Richards*, 1949]. It seems reasonable to suspect that equilibrium dialyzate would cease to exist in soil cavities when p_d approaches this limit. Thus, equilibrium dialyzate may not exist in soils at low water contents, except when created by ultrafiltration. Whether real or imaginary, equilibrium dialyzate is a useful concept and a reference point for computation.

It follows that at point d,

$$\zeta_d = gz_d; \quad \varphi_d = vp_d; \quad \omega_d = -v\Pi_d;$$
$$\text{and} \quad \alpha_d = 0 \quad (14)$$

Point a—This point is found at the air-water interface at a point of zero curvature. Thus, the absolute pressure at this point is equal to the pressure P_a in the atmosphere at this elevation z_a above the datum level.

P_a can be obtained from the barometric equation for an isothermal atmosphere:

$$P_a = P_0 e^{-Mgz_a/RT} \quad (15)$$

where M is the mean molecular weight of air.

Since the gage pressure p_0 is zero at z_0, one finds at point a,

$$p_a = P_0(e^{-Mgz_a/RT} - 1). \quad (16)$$

Since all of the double-layer ions are confined to the liquid phase (the system as a whole is electrically neutral), $\nabla\psi_a = 0$; hence, $\alpha_a = 0$. This result is the key to this paper and deserves closer attention, for it may not be strictly correct. The Gouy-Chapman theory of the double layer does not consider the fine structure of the electric field within the double layer. Instead, it assumes that local distortions, which must occur in the vicinity of each ion, may be neglected and the field may be represented as one dimensional for planar surfaces. Such a field must vanish at the air-water interface. Nevertheless, it is possible (although unlikely, because of the hydration shells of ions) that the outer-most layer would already contain some double-layer ions. The one-dimensional field would then increase abruptly to a finite value as this layer is traversed. Returning to the microscopic viewpoint, it is apparent that this transition is really localized to the position of the ions and would not occur in the intervening areas. Such localized field distortions would, however, be similar in nature to the distortions to be found around ions at the surface of any neutral electrolyte solution and consequently would be of no concern in a consideration of the over-all electric field. With regard to the latter, it is only inside the first layer that the unbalance of charge becomes significant in terms of the one-dimensional field of the Gouy-Chapman theory.

This argument is at best qualitative, and more detailed analysis may prove it to be inadequate. It presents a working hypothesis consistent with the Gouy-Chapman theory and subject to similar limitations but having potentially equal value as a basis for computation.

Accepting these approximations, one obtains

$$\zeta_a = gz_a; \varphi_a = vP_0(e^{-Mgz_a/RT} - 1);$$
$$\omega_a = -v\Pi_a; \text{ and } \alpha_a = 0 \quad (17)$$

Since $\Psi_a = \Psi_d$, it follows that, if $z_a = z_d$

$$\Pi_a = \Pi_d - p_d \quad (18)$$

For the calculation of Π_a see under point *c*. Notice that all other quantities in (17) are measurable.

Point c—The boundary conditions, applicable to the Gouy-Chapman equations for the double layer which must be applied to obtain a solution for parallel plates separated by a distance $2x_c$, are essentially identical with those which must be applied to a system in which the double layer is terminated by an air-water interface parallel to the particle at a distance x_c. In other words, the double layer between parallel, flat, infinite plates is the combined image and mirror image of the double layer present when a flat air-water interface terminates the double layer at a distance half of that which separates the plates. This comparison breaks down if the dimensions of the clay-water system are very small, so that the pressure at the central plane is affected by surface tension and is significantly larger than atmospheric pressure, which exists at the flat air-water interface.

Thus, for a clay-water paste for a body of material which is not too small

$$\zeta_c = \zeta_a \, ; \varphi_c = \varphi_a \, ; \omega_c = \omega_a \, ; \text{and } \alpha_c = \alpha_a \tag{19}$$

Equations have been worked out for such interacting plates which make it possible to estimate ω_c in terms of the surface density of charge of the mineral surface, the concentration of the equilibrium dialyzate, and the separation of the plates (x_c will be taken to represent either the distance from the mineral surface to the central plane at *c* or the film thickness at *a*).

For symmetric electrolytes and ideal behavior

$$\Pi_c = \Pi_d \cosh y_c \tag{20}$$

where

$$y_c = \frac{\nu F \psi_c}{RT}$$

with ν = valence, F charge per gram equivalent, R the universal gas constant, and T the absolute temperature. The parameter y_c can be evaluated in that case from the complete elliptic integral

$$(x_c + x_1)\sqrt{\frac{4\pi}{\epsilon}\Pi_d} = \frac{2RT}{\nu F} e^{-y_c/2} \int_{\varphi=0}^{\varphi=\pi/2} \frac{d\varphi}{\sqrt{1 - e^{-2y_c}\sin^2\varphi}} \tag{21}$$

The parameter x_1 is determined mainly by the surface density of charge Γ in me/cm², and is given approximately by the relation

$$x_1 \simeq \frac{4}{\nu\beta\Gamma} \tag{22}$$

where $\beta = 8\pi F^2/1000\epsilon RT \simeq 10^{15}$ cm/m mole. x_1 is about $4/\nu$ A for montmorillonite, $2/\nu$ *A* for kaolinite and $1/\nu$ A for illite.

Corresponding values of x_c and y_c have been tabulated elsewhere [*Bolt* and *Miller*, 1955].

Point b—This point is located somewhere between parallel interacting plates, not too close to the periphery.

Again

$$\zeta_b = gz_b \tag{23}$$

and

$$\alpha_b = \frac{\epsilon - 1}{8\pi} v(\nabla\psi)_b^2 \tag{24}$$

We are unable to give explicit expressions for the other components in this case, but the following parametric equations in y may be used

$$\omega_b = \omega_c + \frac{v\epsilon}{8\pi}(\nabla\psi)_b^2 \equiv \omega_d \cosh y_b \tag{25}$$

Again noting that $\Psi_b = \Psi_c$

$$\varphi_b = \varphi_c + g(z_b - z_c) + \frac{v(2\epsilon - 1)}{8\pi}(\nabla\psi)_b^2 \tag{26}$$

For this case y_b can be computed from the relationship

$$(x_b + x_1)\sqrt{\frac{4\pi}{\epsilon}\Pi_d} = \frac{2RT}{\nu F} \cdot e^{-y_c/2} \int^{\arcsin e^{-(y_b - y_c)/2}} \frac{d\varphi}{\sqrt{1 - e^{-2y_c}\sin^2\varphi}} \tag{27}$$

values for the incomplete elliptic integral in this expression are tabulated in standard mathematical tables.

If the dimensions of an ideal clay-water system are reduced until it contains only a few particles, the equations given above must be modified to take into account the effects of surface tension on conditions inside the system. This will be considered under the section entitled, *Mixed systems*.

Coarse-grained systems—There can be little doubt that electrical double layers are developed by coarse-grained particles in contact with water. Thus, the analysis of component potentials in proximity of the surface of a clay-size particle is applicable to the surface of a larger mineral particle with the additional consideration of the curvature at the air-water interface and its influence on the pressure just inside the interface.

Point e—This point is found as a curved air-water interface beyond the range of influence of the double layers of nearby particles. Here the classical concepts based on surface tension and film curvature apply. If the surface tension is τ, and the mean radius of curvature is r_e (taken to be negative when the interface is concave on the air side), the gage pressure at e differs from that in adjacent air by an amount $2\tau/r_e$. This leads to

$$\zeta_e = gz_e; \quad \varphi_e = v\left[P_0(e^{-Mgz_e/RT} - 1) + \frac{2\tau}{r_e}\right];$$

$$\omega_e = -v\Pi_e; \quad \text{and} \quad \alpha_e = 0 \qquad (28)$$

In this case, $\Pi_e = \Pi_d$, which is measureable.

Points f and f′—These points are found at curved air-water interfaces in regions influenced by the double layer. The equations for point f are identical to those for point e with a substitution of subscripts. In this case, Π_f may be obtained from double-layer theory, but it also follows that, if $z_f = z_a = z_d$

$$\Pi_f = \Pi_a + \frac{2\tau}{r_f} = \Pi_d - p_d + \frac{2\tau}{r_f}$$
$$= \Pi_d - 2\tau\left(\frac{1}{r_e} - \frac{1}{r_f}\right) \qquad (29)$$

Observe that the osmotic concentration is greater at a than at f.

Point f' is represented by identical equations, but in this case (positive curvature) the osmotic concentration at f' is greater than at a. Comparing equations for f and f' gives

$$\Pi_f - \Pi_{f'} = 2\tau\left(\frac{1}{r_{f'}} - \frac{1}{r_f}\right) \qquad (30)$$

as a general relation between film curvature and concentration at different points on the air-water interface.

Point d—This point is outside the range of the double layers of nearby particles as in the case of point e, and (28) applies with a substitution of subscripts. The mean radius of film curvature at point e is retained, providing $z_d = z_e$, and one obtains

$$\zeta_d = gz_d; \quad \varphi_d = v\left[P_0(e^{-Mgz_d/RT} - 1) + \frac{2\tau}{r_e}\right];$$

$$\omega_d = -v\Pi_d; \quad \text{and} \quad \alpha_d = 0 \qquad (31)$$

Point g—This point is located somewhere in a fully extended planar double layer. In this case the pressure in the water at the outer extremity of the double layer is determined by the film curvature and the surface tension, but the pressure at point g must be calculated. From (11) it follows that

$$\omega_g = \omega_d + \frac{v\epsilon}{8\pi}(\nabla\psi)_g^2 = \omega_d \cosh y_g \qquad (32)$$

From (8) one obtains

$$\alpha_g = \frac{v(\epsilon - 1)}{8\pi}(\nabla\psi)_g^2 \qquad (33)$$

Since $\Psi_g = \Psi_d$ (cf. (31) and (28))

$$\varphi_g = \varphi_d + g(z_g - z_d) + \frac{v(2\epsilon - 1)}{8\pi}(\nabla\psi)_g^2 \qquad (34)$$

The value of $(\nabla\psi)_g$ can be estimated with the help of the double layer theory. For symmetrical electrolytes and essentially planar surfaces, one finds

$$\psi_g = \frac{RT}{\nu F}\ln\left[\frac{\cosh \nu\sqrt{\beta c_d}(x_1 + x_g) + 1}{\cosh \nu\sqrt{\beta c_d}(x_1 + x_g) - 1}\right] \qquad (35)$$

Mixed systems—If small fragments of an ideal clay-water system are scattered through a coarse-grained system, complications may arise if the clay-water sub-systems are sufficiently small. Probably this is rare in nature, but examination of some consequences is of academic interest.

It has already been shown in the preceding section that where the influence of the double layer is felt at a curved air-water interface, the classical condition of constancy of the mean film curvature no longer applies. Figure 2 represents a single pair of parallel clay plates present in a small droplet of water. The plane AA' bisects the space between the plates. Over most of the plane the osmotic concentration of double-layer ions will be essentially uniform, but near the edges it will decrease to a minimum value at the air-water interface. The electric potential varies accordingly. The pressure will vary in somewhat the same manner, increasing from a minimum value at the air-water interface to a maximum value between the plates. Both normal and radial components of the electric field will be zero in the central region, but the radial component will be finite near the periphery, so that α is finite in this region.

A detailed analysis of this system is impractical at this time, since the structure of the double layer in the peripheral zone is not readily obtained. It is

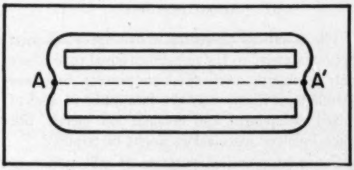

FIG. 2 – Schematic representation of water droplet containing parallel clay plates

apparent, however, that the pressure at every point in this small system will be greater than that in a corresponding large system by an amount no less than $2\tau/r_A$ where r_A is the mean film curvature at A.

A novel consequence of this analysis is that whereas surface tension induces pressure deficits in water present in field-free pores between particles which are in direct contact, it tends to increase the pressure in zero-field regions between particles which are prevented from direct contact with their neighbors by the interaction of their double layers.

It is probable that clay-water sub-systems in mixed systems are generally too large for surface tension to play a significant role in determining the pressure at the central plane between parallel particles, and the assumption that this pressure is atmospheric is probably justified. If this is true, mixed systems have no properties which cannot be estimated from the component parts according to the preceding sections.

NON-IDEAL CLAY WATER SYSTEMS

Expanding lattice minerals are probably the only ones which approach the properties described for ideal clay-water systems. Micaceous minerals, such as illite, might be described as semi-expanding minerals, since repulsive forces act between adjacent particles in the same way as between particles of montmorillonite. The expansion is much less noticeable, since the number of particles per unit volume of solids is much smaller, each particle being an order of magnitude thicker than the individual particles present in montmorillonite. Moreover, micaceous clay minerals can be expected to have terraced rather than simple planar surfaces, so that the distances between opposing faces are not uniform. Blocky or lathlike particles common in kaolinite and attapulgite are even less likely to behave in the manner of the ideal clay-water system described and may approach coarse grained system in general characteristics.

APPROXIMATIONS

The equations presented above apply, at least approximately, to the one-dimensional case where only symmetric electrolytes are present. Standard double-layer theory may also be applied to cases of mixed monovalent and divalent ion species, but some involved calculations might be required.

For most practical purposes it will suffice to proceed as if only symmetric electrolytes were present, and the valence of the electrolyte should be taken as the valence of the cation species present in greatest abundance in the double layer.

If the value of x_c in (21) is small in comparison with $\nu F\sqrt{4\pi/\epsilon\Pi_d}$, (21) and (27) may be simplified, since the concentration of anions between interacting plates will everywhere be small in comparison with cations. In that case, (21), (27), and (12) can be combined to give

$$(d\psi/dx) = \frac{RT}{\nu F}\frac{\pi}{(x_1 + x_c)}\operatorname{cotan}\left[\frac{\pi}{2}\frac{(x + x_1)}{(x_c + x_1)}\right] \quad (36)$$

In Figure 3 examples of the variation of the component potentials in the liquid layer are presented for the case of illite at water contents of approximately 35 pct and 90 pct, dry-weight basis. It is assumed that a symmetric monovalent electrolyte is present with a concentration of 0.01 mol/L in the equilibrium dialyzate.

Figures 4, 5, and 6 have been prepared to show the relationship between x_c, the 'film thickness' for an ideal planar double layer bounded by a flat air-water interface, and the combined solute concentration (moles cations plus moles anions per liter) at the interface. Three different families of curves have been calculated, all having the same (unlabeled) limiting curve for the case of infinitely dilute equilibrium dialyzate. The individual curves

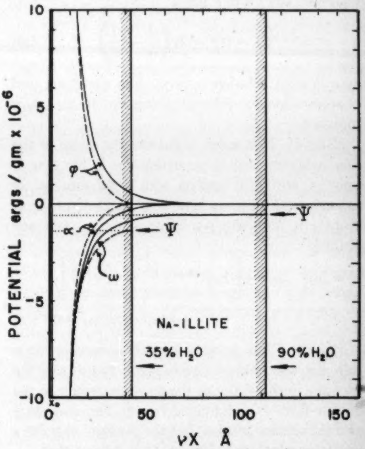

FIG. 3 – Variation of component potentials with distance for ideal clay with film thicknesses corresponding to the indicated water contents

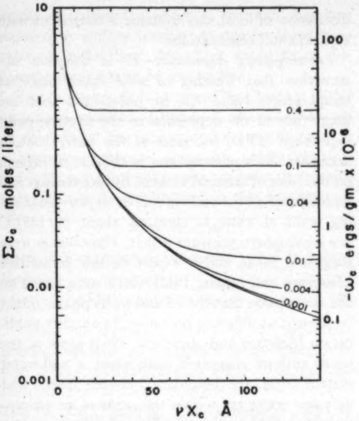

FIG. 4 – Combined concentration at a flat air-water interface bounding a double layer as a function of film thickness x_e and valence ν of the dominant counterion for various nominal concentrations of equilibrium dialyzate in moles/liter; the osmotic component of the total potential at the interface is given on the right-hand ordinate

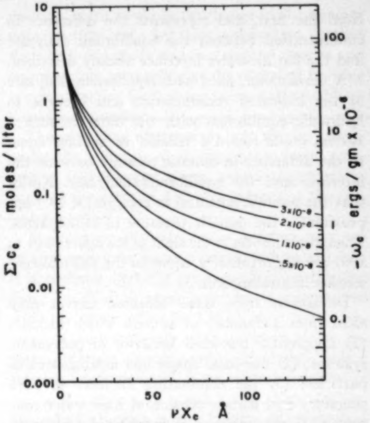

FIG. 5 – Combined concentration and osmotic component of total potential at a flat air-water interface bounding a double layer as a function of film thickness and valence of the dominant counterion for various constant electrolyte contents expressed as milliequivalents of anions per cm² of solid-liquid interface

are labeled according to the nominal concentration of the equilibrium dialyzate in moles per liter.

The first family of curves given (Figure 4) represents relationships calculated for the 'hydraulic-equilibrium case' in which concentration of the equilibrium dialyzate is kept constant. This is intended to simulate the relationship between water content and chamber pressure which might be obtained with a pressure-membrane apparatus in which hydraulic equilibrium is established between water in the soil and equilibrium dialyzate outside the pressure chamber. It is assumed that the membrane is freely permeable to solutes and that the quantity of external solution is such that its concentration is not measurably changed by transfers of water and solutes across the membrane as the system adjusts to equilibrium.

The second family of curves (Fig. 5) represents the relationship calculated for the 'vapor-equilibrium case' in which the quantity of electrolyte present is held constant. Individual curves are identified by the quantity of anions in moles/liter present per unit area of solid-liquid interface in cm².

The third family of curves (Fig. 6) is derived

FIG. 6 – Differences between combined concentrations at a flat air-water interface bounding a double layer and the equilibrium dialyzate for various nominal concentrations of equilibrium dialyzate; the corresponding differences in osmotic component of the total potential are indicated on the right-hand ordinate

from the first, and represents the difference in concentration between the equilibrium dialyzate and the flat air-water interface already described.

A tensiometer, filled with equilibrium dialyzate of the indicated concentration and brought to hydraulic equilibrium with the water in such a system would record a 'tension' or 'suction' equal to the difference in osmotic pressure between the interface and the equilibrium dialyzate. Notice that the osmotic potential in ergs/gm $\times 10^{-6}$ approximates the osmotic pressure in atmospheres. Thus, the numbers to the right of the figure (0.01 to 100) are approximately equal to the soil moisture tension in atmospheres.

Deviations from these idealized curves may arise from a number of sources which include: (1) apparently non-ideal behavior of polyvalent systems; (2) non-ideal shape and arrangement of particles; (3) the dominating influence of pore geometry and surface tension at high water contents; (4) the presence of interparticle forces or bonds which interfere with the normal swelling property of planar particles; and (5) segregation of ideal clay sub-systems into minute portions largely enclosed by an air-water interface.

DISCUSSION

Attempts to fit published data to the curves presented have so far been inconclusive. In almost every instance it is possible to force a reasonable fit by making suitable assumptions with regard to details of materials or procedure omitted from the descriptions given. Other reasonable assumptions would lead to a poor fit, and no conclusions may be drawn. Attention is called to the following points which appear to be pertinent to the acceptance of the analysis given.

Swelling pressure—*Warkentin* and others [1957] found that precompressed suspensions of sodium montmorillonite in 10^{-4} m NaCl gave quantitative agreement between the appropriate curve in Figure 6 and experimental results for the range

$$-(\omega_c - \omega_d) = (0.2 \text{ to } 50) \times 10^6 \text{ ergs/gm.}$$

The data show negligible hysteresis except for the initial dewatering leg. On the other hand, similar experments with calcium montmorillonite show rather large discrepancies between theory and measurement. These discrepancies do not necessarily indicate errors in the concept of the forces acting on the water, but do indicate the presence of factors not accounted for by the simple Gouy-Chapman theory of the electrical double layer. These results are taken to be evidence that the discussion of ideal clay systems is consistent with experimental observations.

Freezing-point depression—It is common observation that freezing of soils takes place at temperatures below the ice point, and that the magnitude of the depression of the freezing-point depression (FPD) increases as the water content decreases. This phenomenon is difficult to explain on the basis of classical ideas of surface tension and its influence on the state of soil water, for the freezing point of water is elevated about (1/133)°C per atmosphere pressure deficit. Hypotheses were suggested in an earlier report of this committee [*Anderson* and others, 1942] which were based on the assumption that the ice and water phases might be present at different pressures. In another publication [*Edlefsen* and *Anderson*, 1943] some of the same authors suggested that when a soil-water system froze, the boundary between frozen and unfrozen water lay within the range of an adsorptive force field so that the film of unfrozen water between the ice and the mineral surfaces was compressed and its freezing point lowered accordingly.

These suggestions strain the credulity. It is difficult to imagine co-existing but isolated ice and liquid water phases except in unusual instances. Nor is there any reasonable suggestion regarding the origin of the long range forces which would be required to produce mutual attraction between ice and mineral surfaces across an intervening layer of water.

The present analysis leads to two new concepts to explain depression of the freezing point. First, the modifying influence of the double layer on the concentration of electrolytes present at the ice water interface is taken into account. If it is assumed that the pressure at this interface is atmospheric (as in the simple clay water system described under *Ideal clay-water systems*), the freezing point would be depressed. Moreover, this freezing point depression in ideal systems would be calculable from Π_c according to the relation

$$\text{FPD}_c = 1.86c_c = \frac{1.86\Pi_c}{RT} = \left(\frac{\Pi_c}{12.06}\right)^\circ\text{C} \qquad (37)$$

when Π_c is in atmospheres and c is in moles liter.

The second concept also depends upon the influence of the double layer, which, in the case described for mixed systems, allows surface tension to induce positive pressures in the regions of lowest concentration (and least freezing-point depression). The effect of the double layer upon concentration and, hence, upon FPD would be as before, but to it would be added the effect of increased pressure induced by surface tension. At present there is no basis for belief that this effect would be of sufficient magnitude to be measurable.

Freezing point data obtained by *Campbell* [1952] have been replotted in Figure 7. His samples were equilibrated at the indicated chamber pressures in a pressure membrane apparatus before freezing. Referring to *Ideal clay-water sxstems*, it appears that for samples equilibrated in this manner

$$\Pi_e = \Pi_d - p_d \qquad (38)$$

where the chamber pressure was $-p_d$. It follows that

$$(\text{FPD} \times 12.06 - \Pi_d) = -p_d \qquad (39)$$

Using the osmotic pressure of the saturation extract reported by Campbell as an approximation of Π_d, the ordinate in Figure 7 should approximate the chamber pressure used for equilibration in each sample. The agreement between measured values and a line drawn to represent 1:1 correspondence between these quantities is probably commensurate with the necessarily crude assumptions made.

If it had been assumed that the liquid phase were present at a pressure less than that of the ice phase by the amount indicated on the ordinate, and further assumed that there was no effect of the double layer upon concentration in the soil solution, there would be no change in the appearance of this plot, but this assumption implies that the liquid phase was in a state of tension and was therefore metastable at the observed freezing temperature, for the freezing point is elevated by a decrease in pressure.

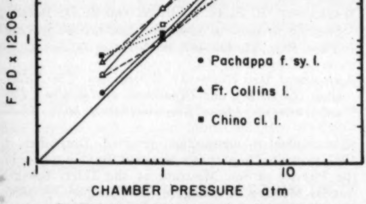

FIG. 7 – Freezing point depression data obtained by Campbell replotted as described in text; open symbols represent unpuddled samples; solid symbols represent puddled samples; samples were equilibrated in a pressure membrane apparatus at the pressure indicated prior to freezing

The remaining alternative, that the ice phase, under the influence of an adsorptive force, compresses the unfrozen water, would require pressures of the order of 150 atmospheres at the ice-water interface.

The pressure at the ice-water interface may not be atmospheric for various mechanical reasons, but it is probable that the pressure effect on freezing point (−1°C/133 atm) is trivial in comparison with the solute effect (−1.86°C/mole/liter). Because of the uncertainty of the pressure at the ice-water interface, freezing point depression, unlike relative vapor pressure, is an inexact measure of the total potential of water in soil. Nevertheless, the principal errors in the freezing point method are probably due to (1) uncertainties in quantity of electrolyte present, (2) the estimation of corrections for the amount of water frozen, and (3) corrections to 'field temperature.' Since the segregation of ice is roughly equivalent to the removal of water by distillation, the curves given in Figure 5 may be used in connection with corrections for the amount of water frozen.

Using Figure 4 to estimate Σc_e at the onset of freezing and Figure 5 to estimate the correction for the amount of water frozen, it should be possible to estimate from one of the points in Figure 7 the freezing points expected at other water contents. Unfortunately, Campbell did not report water contents for the samples frozen and this test of the analysis cannot be applied.

'Tension' in soil water—By convention, water in which the pressure is less than atmospheric is referred to by soil scientists as existing in a state of tension. This is not literally true unless the 'tension' or suction exceeds one atmosphere. It has been shown that water has, at least under favorable conditions, considerable tensile strength. It is also common knowledge that in many systems, especially when the water contains dissolved gases, the tensile strength is apparently nil, for as the absolute pressure approaches the vapor pressure of the water, bubbles of air and water vapor form, 'breaking' the liquid phase. For example, tensiometers used in soil investigations fail as the pressure deficit in the tensiometer cup approaches one atmosphere. It seems likely that the tensile

strength of water in soil would have a similar limitation. This contention should be subject to test, and deserves attention. Recent results of *Lieberman* [1957] encourage the belief that bubbles would be readily nucleated in soil and might persist in quite small pores.

This point is probably academic, however, for the curves shown in Figures 4, 5, and 6 indicate that relatively small proportions of clay-sized particles in a soil can retain substantial quantities of water, comparable to those observed in practice, without resort to the conventional capillary concepts so useful in the case of water retention in large pores. The principles of capillarity apply to micropores but are probably of little consequence in comparison to the retention of water in the double layer itself.

Since previous proposals for explaining the freezing-point depression of water in soil appear untenable and since those advanced in this paper depend upon the presence of double-layer ions, it seems reasonable to suspect that in the range of moisture contents in which freezing-point depressions are measurable, little if any of the water is present in regions in which the double layer is sensibly absent.

We infer that the existence of water in a metastable liquid phase in soils is improbable under ordinary circumstances. We suspect that the fraction of water which is actually in tension is never large except perhaps at very high water contents and small tensions. This conclusion was also reached by Edlefsen and Anderson. We regard apparently large values of soil moisture tension or soil suction to be artifacts accounted for by the influence of the electrical double layer. We acknowledge that it is possible to isolate systems in which water can be made to exhibit great tensile strength, but we doubt that such systems are common in soil.

The discussion presented cannot be regarded as proof of the concepts of the components of the total potential as used in this paper. Instead, the discussion is intended to assist the reader in his evaluation of this analysis as a logical restatement and improvement of earlier ideas. Experimental tests of some of the concepts are possible and it is expected that the value and limitations of this treatment will be demonstrated in due course.

Typical Solutions of the Differential Equations of Statistical Theories of Flow through Porous Media

A. E. SCHEIDEGGER

Abstract—The description of the miscible displacement process in porous media (such as occurs, for example, during the pollution of ground-water resources with wastes) by methods of statistical mechanics has met with considerable success. The method usually employed is that of considering the motion of each particle through the medium as a random-walk process. Recently, however, it has been suggested that autocorrelation should also be taken into account and a differential equation allowing for this effect to take place has been arrived at. The purpose of the present paper is to give solutions of the autocorrelation equation for some typical cases and to compare the result with that obtained for the random walk model without autocorrelation. These cases refer to the passage of a thin slug of 'tagged' fluid through a porous medium and to the intrusion of a sharp concentration front into a medium. It is shown that autocorrelation has the effect that a concentration-discontinuity proceeds at a finite speed into the medium which cuts off the infinite 'tail' of the solution without autocorrelation. Graphs to illustrate the situation are given.

Introduction—The statistical method has met with considerable success in explaining the experimentally observed effect of dispersion during the passage of a fluid through a porous medium. This effect is particularly important in the displacement of a fluid by another with which it is miscible. Such cases occur during the intrusion of salt water into the fresh-water lens beneath oceanic islands and also during the extraction of petroleum from reservoirs by solvents.

Since statistics were first introduced into displacement studies (for a review, see *Scheidegger* [1957]), a variety of theoretical models has been proposed. Such statistical models rest, as had been outlined earlier, [*Scheidegger*, 1958b] on three types of assumptions: (1) one has to choose an ensemble with which to do statistics; (2) one has to choose the type of statistics which is to be used, and (3) one has to choose the microscopic flow law to which each small volume of fluid is subject. Among the various models that have been proposed, it is of particular interest to weigh those which differ by the type of statistics which they employ, since this is governed by properties of the porous medium. The microscopic flow law depends on the flow regime and on the fluid, but the statistics depends directly on the assumed properties of the porous medium.

A decision between the various possible models can only be made if appropriate experiments are attempted. Experiments that can be performed easily fall into two classes: (1) testing the passage of a thin slug of tagged fluid through a porous medium, and (2) testing the intrusion of an originally sharp front of tagged fluid into untagged fluid. All experiments, of course, refer to linear set-ups; that is, one has only one space coordinate.

In order to provide a basis for comparison of the experiments with the theory, it is necessary to obtain the appropriate solutions of the differential equations for the possible statistical models. It is the purpose of the present paper to do this.

The statistical models—The statistical models that have been proposed to investigate the flow through porous media are essentially two in number.

In both cases one gives a fixed time t and one asks for the probability $\psi(x, t)$ for a particle to be at a given spot at that time. In accordance with the common custom, one splits the total time t into small intervals τ; the progress of a particle during any interval τ is some random function and the summation of all infinitesimal 'progresses' yields the position of the particle at time t. If the mean progress during τ is $\bar{\xi}$, and if the deviation from $\bar{\xi}$ during τ is random, then the function $\psi(x, t)$ will be Gaussian, simply because of the central limit theorem of probability theory. It can be represented most easily in a system of coordinates $x't'$ in which $\int x'\psi(x', t)\, dx' = 0$, that is, in a system that moves with the 'mean' flow. The velocity v of the mean flow depends on the external conditions, such as pressure drop, as well as on properties of the porous medium and the fluid.

In the present case (Case A) the basic flow equation is therefore

$$\frac{\partial\psi}{\partial t'} = D\frac{\partial^2\psi}{\partial x'^2} \tag{1}$$

$$x = x' + vt' \tag{2a}$$

$$t = t' \tag{2b}$$

In the coordinates x, t this is

$$\frac{\partial \psi}{\partial t} = D \frac{\partial^2 \psi}{\partial x^2} - v \frac{\partial \psi}{\partial x} \tag{3}$$

Remember that v as well as D are constants in any one linear experiment where the conditions for the total flow are held steady; v and D, however, may depend on the pressure drop.

Case A corresponds essentially to a random-walk picture of flow through porous media. One can modify this idea somewhat by assuming that there is autocorrelation between subsequent time-steps. This case has been discussed by the author [*Scheidegger*, 1958a] and it was shown that, in the moving coordinate system (2) one ends up with a telegraph equation instead of with a diffusivity equation. This represents the Case B, thus

$$\frac{\partial \psi}{\partial t'} = D \frac{\partial^2 \psi}{\partial x'^2} - A \frac{\partial^2 \psi}{\partial t'^2} \tag{4}$$

In terms of x, t, this yields

$$\frac{\partial \psi}{\partial t} + v \frac{\partial \psi}{\partial x} = D \frac{\partial^2 \psi}{\partial x^2} - A \left[v^2 \frac{\partial^2 \psi}{\partial x^2} + 2v \frac{\partial^2 \psi}{\partial x \partial t} + \frac{\partial^2 \psi}{\partial t^2} \right] \tag{5}$$

Again, the quantities A, D, and v depend on the other dynamic parameters such as pressure drop, according to the microdynamic assumptions which are being made. In Case A as well as in Case B, one can therefore introduce a variety of assumptions and come up with a variety of models. However, if an 'overall steady state' be considered, that is, a state in which the total flow velocity is steady, then these various parameters are constants.

Progress of a slug—In order to evaluate the two models of miscible displacement, they must be compared with experiments. As stated in the introduction, two types of linear experiments can easily be performed. Starting with a very thin slug of tracer substance at $x = 0$, one can observe its spreading; similarly, starting with a sudden jump in concentration of tracer substance at $x = 0$, one can observe the flattening of the saturation drop.

We shall start with a consideration of the progress of a thin slug in the two cases. This requires that the fundamental differential equations pertaining to each of the two cases be solved for the initial condition.

$$\psi(x, 0) = m_0 \delta(x) \tag{6}$$

where δ denotes the Dirac delta function and m_0 (which we shall set equal to unity in the following lines) is the total amount of tracer substance contained in the slug. Then, ψ is a linear density (= amount/unit length) and therefore proportional to the concentration of tracer per unit length.

The solution for Case A is well known, since the basic equation is simply a diffusivity equation. It is [*Crank*, 1956]

$$\psi = \frac{1}{(4\pi D t)^{\frac{1}{2}}} \exp\left(-\frac{x'^2}{4Dt}\right) \tag{7}$$

with, as usual

$$x' = x - vt \tag{8}$$

v being the pore velocity of the total flow.

The shape of the curves representing $\psi(x)$, for various values of t, is shown in Figure 1.

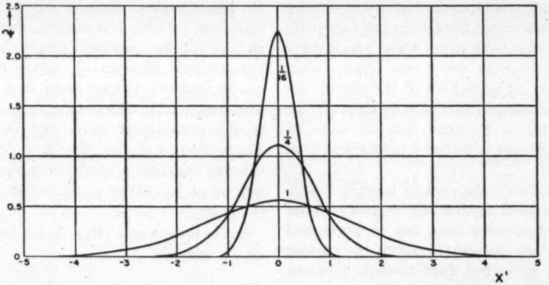

FIG. 1 – Shape of a slug of tagged fluid passing through a porous medium if no autocorrelation is taken into account

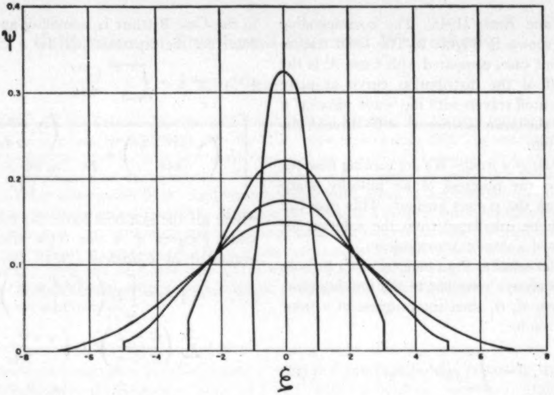

FIG. 2 – Shape of a slug of tagged fluid passing through a porous medium if autocorrelation is taken into account

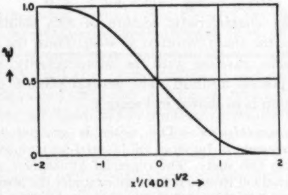

FIG. 3 – Shape of a concentration front during miscible displacement in a porous medium without autocorrelation

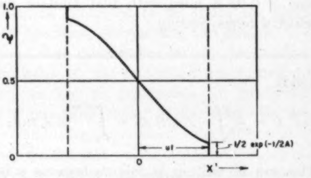

FIG. 4 – Shape of a concentration front during miscible displacement in a porous medium with autocorrelation

We turn next to Case B. In this instance, one has to solve the telegraph equation (4) for the boundary condition (6). The solution for this problem has been given by *Goldstein* [1951]. It is

$$\left.\begin{aligned} \psi(x', t) &= \frac{e^{-t/2A}}{4Au}\left[I_0(Y) + \frac{t}{2A}\frac{I_1(Y)}{Y}\right] \\ &\qquad\qquad \text{for } |x'| < ut \\ &= 0 \qquad\qquad \text{for } |x'| > ut \end{aligned}\right\} \tag{9}$$

with

$$Y = (u^2t^2 - x'^2)^{\frac{1}{2}}/(2Au) \tag{10}$$

$$D = Au^2; \qquad u = (D/A)^{\frac{1}{2}} \tag{11}$$

$$x' = x - vt \tag{12}$$

and I_0, I_1 are Bessel functions with imaginary argument

$$I_0(x) \equiv J_0(ix) = \sum_{m=0}^{\infty} \frac{(\frac{1}{2}x)^{2m}}{(m!)^2} \tag{13}$$

$$I_1(x) \equiv -iJ_1(ix) = \sum_{m=0}^{\infty} \frac{(\frac{1}{2}x)^{2m+1}}{m!(m+1)!} \tag{14}$$

In order to evaluate the above formulas, let us set

$$\xi = x'/(2Au) = x'/(2\sqrt{AD}) \tag{15}$$

and

$$\tau = t/(2A) \tag{16}$$

Then the solution becomes

$$\left.\begin{aligned} \psi(\xi, \tau) &= \tfrac{1}{2}e^{-\tau} \\ &\cdot\left[I_0(\sqrt{\tau^2 - \xi^2}) + \tau\frac{I_1(\sqrt{\tau^2 - \xi^2})}{\sqrt{\tau^2 - \xi^2}}\right] \\ &\qquad\qquad \text{for } \xi < \tau \\ &= 0 \qquad\qquad \text{for } \xi > \tau \end{aligned}\right\} \tag{17}$$

which is also properly normalized. The values of ψ have been calculated for a representative number of the arguments, using the tables of functions of *Jahnke* and *Emde* [1945]. The corresponding curves are shown in Figure 2. The chief feature of the present case, compared with Case A, is the sharp cutoff of the distribution curve at early times. The cutoff travels with the 'wave velocity' u (referred to the mean position $x' = 0$) through the porous medium.

The progress of a front—We are turning now our attention to the progress of an initially sharp front through the porous medium. This case can immediately be calculated from the solution for the progress of a slug by superposition.

Denote the solution for a slug by $\sigma(x', t)$ (note that we are always referring to the moving coordinate system x', t), then the progress of a front is simply given by

$$\psi(x', t) = \int_{-\infty}^{0} \sigma([x' - \zeta], t)\, d\zeta \qquad (18)$$

if originally (at $t = 0$) all space $x' < 0$ (this is also $x < 0$) is filled with that kind of fluid to which ψ refers. Setting

$$x' - \zeta = \eta \qquad (19)$$

yields

$$\psi(x', t) = -\int_{\infty}^{x'} \sigma(\eta, t)\, d\eta = \int_{\eta=x'}^{\eta=\infty} \sigma(\eta, t)\, d\eta \qquad (20)$$

This can be written as follows because σ is normalized and symmetrical with regard to $x' = 0$

$$\left.\begin{aligned} \psi(x', t) &= \tfrac{1}{2} - \int_{\eta=0}^{\eta=x'} \sigma(\eta, t)\, d\eta \quad \text{for} \quad x' > 0 \\ &= \tfrac{1}{2} + \int_{\eta=x'}^{\eta=0} \sigma(\eta, t)\, d\eta \quad \text{for} \quad x' < 0 \end{aligned}\right\} \qquad (21)$$

For the Case A this yields [*Crank*, 1956]

$$\begin{aligned} \psi(x', t) &= \tfrac{1}{2} - \int_0^{x'} \frac{1}{(4\pi D t)^{\frac{1}{2}}} \exp\left[\frac{-\eta^2}{4Dt}\right] d\eta \\ &= \tfrac{1}{2} - \int_0^{x'/\sqrt{4Dt}} \frac{1}{\sqrt{\pi}} e^{-z}\, dz \\ &= \tfrac{1}{2} - \tfrac{1}{2} \operatorname{erf} \frac{x'}{\sqrt{4Dt}} \end{aligned} \qquad (22)$$

where erf denotes the error function. The latter is well known; tables are available. The general appearance of the solution (22) is shown in Figure 3.

Finally, we investigate the progress of a front in the Case B (that is, assuming autocorrelation). Inserting the expression (9) for σ into (22) yields

$$\psi(x', t) = \tfrac{1}{2} - \int_{\eta=0}^{\eta=x'} \frac{e^{-t/2A}}{4Au} \cdot \left[I_0\left(\frac{\sqrt{u^2t^2 - \eta^2}}{2Au}\right) + \frac{t}{2A} \frac{I_1\left(\dfrac{\sqrt{u^2t^2 - \eta^2}}{2Au}\right)}{\dfrac{\sqrt{u^2t^2 - \eta^2}}{2Au}} \right] d\eta \qquad (23)$$

where all the symbols have the meaning defined under *Progress of a slug*. This integral has been evaluated by *Goldstein* [1951], the result is

$$\left.\begin{aligned} \psi(x', t) &= \tfrac{1}{2} e^{-t/2A} \left[I_0\left(\frac{\sqrt{u^2t^2 - x^2}}{2Au}\right) + 2\sum_{n=1}^{\infty} \left(\frac{ut - x'}{ut + x'}\right)^{\frac{\eta}{2}} I_n\left(\frac{\sqrt{u^2t^2 - x'^2}}{2Au}\right)\right] \\ &\qquad\qquad \text{for} \quad 0 < x' < ut \\ &= 0 \qquad\qquad \text{for} \quad x' > ut \end{aligned}\right\} \qquad (24)$$

and corresponding values for $x' < 0$.

The characteristic feature of this solution is again the sharp cutoff at $x' = ut$. Thus, the cutoff is again traveling with the 'wave velocity' u into the porous medium. The general picture of the solution is as shown in Figure 4.

Calibration of Five Small Forested Watersheds

K. G. REINHART

Abstract—On the Fernow Experimental Forest in West Virginia, five forested watersheds, 38 to 96 acres in area, have been gaged by the U. S. Forest Service since 1951. The watersheds are close together, for the most part contiguous, and are similar in topography, soil, forest cover, and stream-flow characteristics. The methods and problems of calibration should interest other investigators in this field because seldom has a group of watersheds been calibrated for forest watershed research to determine the effects of a range of cutting treatments. After calibration, four watersheds will be cut over, using four different cutting practices. One watershed will be used as a control. Effects of treatment on stream flow will then be measured. Methods of Wilm and of Kovner and Evans were used to determine length of calibration period based on an analysis of annual, monthly, peak, and low flows. Problems of treatment assignment are discussed.

Introduction—The effect of different types of forest management on stream flow is being investigated by the Mountain State Research Center of the Northeastern Forest Experiment Station, U. S. Forest Service, on the Fernow Experimental Forest in Tucker County, near Parsons, W. Va.

Five forested watersheds, ranging from 38 to 96 acres in area, have been continuously gaged since May 1951 (Fig. 1; 80 chains = one mile). V-notch weirs (120°) and continuous water-stage recorders are used. Water quality, precipitation, and soil-moisture content are also being measured.

The watersheds, supporting a 50-year old stand of hardwood timber, have been undisturbed for several decades. Slopes are steep; soils are stony and for the most part shallow.

For calibration of these watersheds, a relationship was established between stream-flow measurements for a period of years in each watershed to be treated and concurrent measurements in another watershed, the control. An analysis was made testing the predictive value of the relationship, to determine (1) the standard error of estimate of the prediction, and (2) the number of observations after treatment required to establish the significance of a difference considered to be of practical importance.

Analytical methods for determining the adequacy of calibration of annual discharge from small watersheds have been presented by *Wilm* [1949] and by *Kovner* and *Evans* [1954]. In this paper application of these methods to peak flows and low flows as well as annual discharge is discussed.

After calibration, four of the Fernow watersheds will be cut over, each by a different system. These systems range from a commercial clearcut with skid roads at maximum operable grades to a conservative selection system (intensive forestry) with skid-road grades not exceeding ten per cent and with provisions for road drainage. One watershed will be left in its undisturbed state as a control. After treatment, stream-flow measurements will be continued to determine the effect on water quantity, distribution, and quality.

During the calibration period, stream-flow characteristics of one watershed are related to another, leading to expressions for predicting values of one from values of the other. We are using straight-line regressions after determining that they fit the data well. For example, based on five years of record, the equation $Y = 0.35 + 0.91X$ enables us with a certain degree of accuracy to predict the annual flow in area-inches of Watershed 1 (Y) from that of Watershed 3 (X).

Length of calibration period—One problem faced, as in all such experiments, was to determine the proper length of the calibration period based on acceptable error. Too short a calibration period would lead to inconclusive results. Too long a calibration period results in unnecessary expense. Our problem is complicated by the fact that the period for measurement of treatment effects will be of limited duration: after logging, the watersheds will recover and effects will diminish. We are thinking in terms of a period of two or three years during which effects of treatment will be at or near a maximum.

Kovner and Evans prepared a graphical solution of Wilm's equation for determing the minimum length of the calibration period. Modified to include a larger number of observations, their graph is reproduced in Figure 2. The horizontal axis shows the number of observations in the calibration period. The vertical axis is the squared ratio:

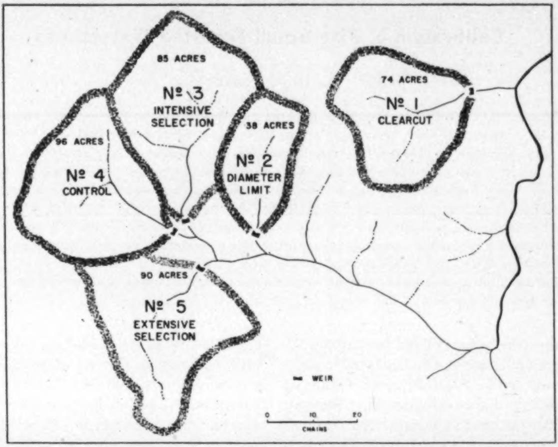

FIG. 1 – Locations of the five gaged watersheds on the Fernow Experimental Forest, showing proposed treatments

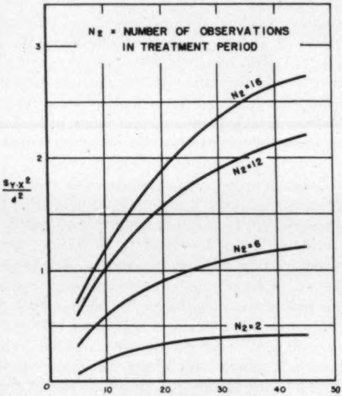

FIG. 2 – Graph for determining duration of calibration and treatment periods, revised from *Kovner* and *Evans* [1954]

standard error of estimate divided by the smallest worthwhile difference. The graph shows a family of curves. Given the number of observations in the calibration period and a value for $s_{y \cdot x}^2/d^2$, the number of observations needed in the treatment period can be read or interpolated.

To use this method, certain assumptions must be made. First, a value must be assigned for d, the smallest worthwhile difference. This might be the smallest difference expected as a result of treatment, based on experience, or a difference due to treatment of such a magnitude that if it is not reached the investigator is willing to forego determination of its significance. Another assumption made, and open to some question, is that variances after treatment will be of the same magnitude as those before treatment.

Analysis—Five years of data were analyzed as a basis for deciding the length of the calibration period and assignment of treatments to individual watersheds. Annual and monthly water flows, peak flows, and low flows were analyzed. Water quality was not analyzed because from previous studies at the Fernow Experimental Forest and elsewhere there seems little doubt that changes in quality, such as turbidity, that result from treatment will be significant.

Mean annual flow ranged from 20 to 27 area-inches for the five watersheds. Regression equations were computed to predict annual flow of each of the watersheds from each of the others; best predictions were obtained with Watershed 3 as the control.

TABLE 1 – *Calibration of four watersheds on Watershed 3; correlation coefficients and errors of estimate*

Item	Watershed							
	1		2		4		5	
	Cor. coef.	Error of est.	Cor. coef.	Error of est.	Cor. coef.	Error of est.	Cor. coef.	Error of est.
Annual flow (error of estimate in area inches)	0.99993	0.055	0.995	0.592	0.996	0.493	0.9988	0.326
Peak flow (error of estimate in csm[a])	0.984	3.72	0.990	3.67	0.990	2.42	0.975	4.86
Low flow (error of estimate in number of days flow less than 0.05 csm[a])	0.998	3.92	0.995	5.35	0.997	4.32	0.995	5.03

[a] Cubic feet per second per square mile.

For the four regressions predicting flow from Watershed 3, the errors of estimate ranged from 0.05 to 0.59 area-inch of water (Table 1). Correlation coefficients ranged from 0.995 to 0.99993. Using the procedure described, with five years in the calibration period and Watershed 3 as the control, one or two years would be required in the treatment period of each of the other watersheds to establish significance at the five per-cent level of a ten percent change in flow of the treated watershed (Table 2). We will be willing to forego determination of its statistical significance if change in flow is less than ten per cent.

With five years of record, there are of course only five observations of annual flow for each watershed, a small number for regression analysis. Therefore, consideration was given to analyzing monthly flows, giving 60 observations in five years. Analysis similar to that already given indicated that, with Watershed 3 as the control, only two to six months would be required to establish significance of a ten per-cent change at the five per-cent level. However, there are objections, often referred to as 'serial correlation', to use of monthly data in this way. For this reason reliance was not placed upon analysis of data by months.

TABLE 2 – *Calibration of four watersheds on Watershed 3; years required in treatment period with calibration period of five years*

Item	Smallest worthwhile difference	Watershed			
		1	2	4	5
	pct	yr	yr	yr	yr
Annual flow	10	1	2	2	1
Peak flow[a]	10	2 (14)	2 (11)	1 (7)	2 (16)
Low flow	20	2	3	2	4

[a] Years required based on average occurrence of peaks in calibration period. Required number of observations (peaks) given in parentheses.

TABLE 3 – *Calibration of four watersheds on Watershed 4; years required in treatment period with calibration period of five years*

Item	Smallest worthwhile difference	Watershed			
		1	2	3	5
	pct	yr	yr	yr	yr
Annual flow	10	2	3	2	1
Peak flow	10	3 (25)	2 (19)	1 (8)	3 (24)
Low flow	20	1	3	3	3

Basic data used in the peak-flow analysis were the peaks at each watershed on 45 occasions when flow of Watershed 3 exceeded ten cu ft/sec mi^2. Peak flows ranged up to 180 cu ft/sec mi^2 and averaged between 21 and 29 cu ft/sec mi^2 for the five watersheds. Regressions were computed to estimate peaks of each watershed from peaks of each of the others. With Watershed 3 as the control, analysis indicates that seven to 16 peaks would be required in the treatment period to establish the significance (at five per-cent level) of a ten per-cent change due to treatment. In the calibration period, there was an annual average of nine peaks of the size included in the analysis. Thus the required treatment period might be about two years.

More difficulties were encountered in the analysis for low flows than in the others. First, it was difficult to decide upon a good measure of low flows. After trial runs using several different approaches, analysis was based upon number of days in the year when flow was 0.05 cu ft/sec mi^2 or lower. For the five years on five watersheds, number of such days varied from 3 to 166. Analysis indicates that, with Watershed 3 as the control, two to four years in the treatment period will be required to establish the significance at the five per-cent level of a 20-pct change in number of days. We are still trying to find a better measure for low flows.

Decisions made—Based on the analysis, we decided to wait until one additional year of record, making six in all, has been obtained before starting treatment. The measurement of low flows gives the most concern. However, results of experiments elsewhere indicate the probability that the effect of treatment on low flows may be greater proportionally than for annual flows.

For several reasons, treatments assigned to individual watersheds were not at random. This made our statistician advisors uneasy, but they finally agreed. Watershed 3 was originally chosen as the control because generally it gave the highest correlations; Watershed 4, well correlated with Watershed 3, was designated for the intensive forestry practice, the least drastic treatment.

However, a proper road for the intensive practice could not practicably be constructed in Watershed 4 without crossing into Watershed 3. Therefore, Watershed 4 was made the control, and Watershed 3 was assigned the intensive forestry practice since a road could be built into Watershed 3 without infringing upon adjacent watersheds. (Table 3 shows years required in treatment period with Watershed 4 as the control). Watershed 1 was chosen for clear-cutting, a destructive practice, for the compelling though unscientific reason that of all five watersheds it is the only one situated below the reservoir of the nearby town of Parsons. Watershed 1 was well correlated with Watershed 4. Thus, the two extremes of treatment were assigned to the watersheds best correlated with the control. The intermediate treatments, a diameter-limit cut and extensive forestry, were assigned to Watersheds 2 and 5.

Conclusions—Five years of record showed remarkably good correlation in stream-flow characteristics of the five gaged watersheds. The methods of Wilm, and Kovner and Evans proved suitable for the analysis of data in this experiment and led to an apparently sound evaluation of necessary length of calibration period. A final evaluation of the methods used cannot be made, of course, until after the treatment period.

A Note on the Dispersion of a Salt-Water Boundary Moving through Saturated Sand

ERIK ERIKSSON

Abstract—Theoretical aspects on this problem are presented referring in particular to a recent work by *Day* [1956]. The theoretical approach by Day is criticized because it involves a time-dependent dispersion function in a stationary flow. It is pointed out that the dispersion in an isotropic medium should be limited and depend only on the soil material whereas in an anisotropic medium the dispersion is expected to depend also on the length of travel of the front.

In a recent paper in this journal, *Day* [1956] discusses the dispersive effects that can be noted in an advancing salt-water boundary moving through saturated sand. As this phenomenon cannot be explained by simple molecular diffusion it is of considerable theoretical interest apart from its practical consequences. To distinguish it from molecular mixing the name longitudinal mixing has been proposed, and at least during short time intervals, its effect far exceeds that of molecular diffusion.

The longitudinal mixing has, as Day points out, been known for some time and has been studied to some extent recently by *Kaufman* and *Orlob* [1956] in a work on the possible use of tracers for studying ground-water flow rates. The explanation of the phenomenon generally accepted is that on a microscale the velocity distribution along true streamlines of a laminar flow through porous soil must be highly variable depending upon how close to particle surfaces the streamlines run. Day accepts this explanation but assumes also that the average velocity along a streamline differs from the bulk velocity, referring to the conditions in a capillary tube. He progresses by applying statistical reasoning and arrives at the conclusion that the dispersion of a moving salt-water front can be described by the common diffusion equation, $\partial C/\partial t = D\nabla^2 C$, where C is the bulk concentration and D is the factor of dispersion and has the same dimension as a diffusion coefficient. His experimental data also fit a solution to this differential equation which, however, is no proof that the differential equation has any physical significance in the case considered. It merely indicates that the dispersion of the front can be described by an integrated probability function of bulk concentration. There is a strong reason to suspect that the differential equation used by Day is improper because it is a function of time. The streamline pattern in laminar flow is fixed by the geometry of the arrangement of pores through which the flow takes place and should be independent on the rate of flow as long as the flow is laminar. The longitudinal mixing should therefore not be a function of time but, if any, of the distance of flow. Hence, the factor of dispersion D in the differential equation can have no physical meaning as it will depend on the average rate of flow. This is actually demonstrated by the experimental data Day refers to as will be seen in the following.

As the data fit an integrated probability function it is obviously possible to relate the standard deviation σ of this probability function to the factor of dispersion D by $\sigma = \sqrt{2Dt}$. In the first experiment at a flow rate of 1.811 cm min^{-1} Day finds that D must be 0.02 cm^2 min^{-1} to fit the observed dispersion of the front. In the second experiment the flow rate was 0.626 cm min^{-1} and the calculated $D = 0.080$ cm^2 min^{-1}. As the distance of flow in both experiments was 26 cm it is possible from these data to calculate $\sigma = \sqrt{2Dt}$ and it becomes 2.40 cm in the first experiment and 2.58 cm in the second, thus practically the same. Obviously only σ, which can be called the characteristic dispersion, has any physical meaning in this case as it represents a constant that presumably is related to the particle size. This is at least implied by its dimension.

The basic assumption made by Day that the average velocity along a streamline differs from the bulk velocity has not been verified in his experiments. It can be proved only by determining the characteristic dispersion σ for different distances of flow.

Before discussing the physical interpretation of σ further, the question about the velocity distribution along true streamlines in laminar flow should be taken up. In the case of flow in a capillary tube the picture of the flow is simple, and it can be inferred that the dispersion must increase with the distance of flow as Day also inferred. It should be noted, however, that if flow took place in such capillaries it would represent a highly anisotropic medium as permeability in any other direction is zero. In a soil particles will be more or less randomly arranged and consequently also the pores through which water flows. In the extreme case one could imagine a completely random arrangement of pores and consequently a completely isotropic permeable material. There would be no favored paths for the streamlines as the pores are branching in any direction in a random manner. Following a streamline one would expect it to go sometimes in the center of a pore, sometimes close to a particle surface but most of the time in any position between these two extremes. The average velocity along any streamline can be expected to be the same as the bulk velocity. The distance s traveled along a streamline can be related to the time and velocity by $ds = v\,dt$ so the average velocity between two points s_1 and s_2 along the streamline can be formulated

$$\bar{v} = \int_{s_1}^{s_2} ds \Big/ \int_{s_1}^{s_2} ds/v$$

If $\bar{v}$ becomes practically constant for a finite distance $\Delta s = s_2 - s_1$ and equal to the bulk velocity, the quantity Δs can be related to the characteristic dispersion σ discussed earlier. One would expect that in the extreme case for $\Delta s = 6\sigma$, $\bar{v}$ would be equal to the bulk velocity but in most cases a smaller distance is required. This is the physical interpretation of σ in the isotropic case. The diffuse front can be pictured as being derived from the originally plane front by needle-like deformations in the direction of flow, the deformations being due to different velocities. The deformation is, however, kept within a certain width 6σ all the time though the topography changes with the flow. The originally plane front can be regarded as a highly improbable case of this ever-changing surface.

If $\bar{v}$ in the formula above should attain a value different from the bulk velocity, which would happen in an anisotropic medium, things become more complicated as then the distribution of average velocities enters the picture. One would expect that for short distances of flow the integrated probability function should well picture the deformation of the front, but for long distances of flow the distribution of average velocities would dominate giving a different picture of the front, maybe something like that for a capillary tube. So there are apparently two basically different processes that can cause longitudinal mixing. Unfortunately, the effect of one cannot be simply superimposed on the effect of the other as one process is dispersive in nature and the other advective.

For the dispersive process one would expect a linear relation between σ and the particle size d. The soil material used by Day had most of the particles in the size range 1–2 mm or say 0.15 cm as an average. Writing $\Delta s = 6\sigma = kd$ where d is the particle diameter, it is seen, using $\sigma = 2.5$ cm that k becomes 100. Due to overlapping of particles when projected one would expect that for a distance 6σ a streamline has to pass about 150 particles. This means that in the most extreme cases the average velocity along a streamline is reached after passing about 150 particles but more frequently after passing a smaller number.

The longitudinal mixing discussed above concern small scales but a similar reasoning can apparently be applied to larger scales where stratification of the soil material causes variations in the average flows discussed above. Not only stratification of soil material can contribute but also structural elements found in soils as results of soil-forming processes. On a larger scale the dispersive effects will also be larger as demonstrated by the field experiments by *Kaufman* and *Orlob* [1956]. There is thus a formal resemblance between dispersive forces in ground-water flow and in the atmosphere, namely that they are proportional to the scale considered.

A Note on the Differential Equation of Steady, Gradually Non-Uniform Flow in Open Channels

HSIN KUAN LIU

Abstract—This note is intended to clarify the sign convention used in the derivation of the differential equation for steady, gradually non-uniform flow in open channels. This clarification is accomplished through the proper use of the reference axis. Such an equation is known to have special forms for various channel shapes. Equations for both the prismatic and non-prismatic channel are summarized.

Non-uniform flow may best be defined by first explaining uniform flow. Uniform flow in an open channel can be established if the channel has the following characteristics: relatively long, of uniform roughness, and geometrically prismatic, that is, a constant slope, alignment, and cross section. Under such conditions, a steady, gravitational flow will have a uniform depth. Therefore the flow area and the mean velocity will remain constant along the flow direction. The energy slope S_e, the water-surface slope S_w, and the bottom slope S_0 have the same value.

In the case where the characteristics of a channel are not as stated above, uniform flow is no longer possible. The flow is then called non-uniform. The conditions necessary for uniform flow to exist are quite severe. The flow in most waterways is not uniform. The following discussion is limited to the case of gradually non-uniform flow, that is, the non-uniformity of the flow is appreciable over a relatively long distance.

The differential equation for steady, gradually non-uniform flow in open channels has been reported in various forms in books of hydraulics [*Rouse*, 1950, p. 610]. Students of hydraulics have found some difficulty in understanding the derivation of such an equation. The difficulty is mainly from two sources: (1) the sign convention for the channel slope, and (2) the sign convention for the energy gradient. The purpose of this discussion is to clarify the derivation by using a simplified sign convention.

The total energy per unit weight of a flow with a uniform velocity V can be written as (see Fig. 1, the channel has a moderate slope)

$$E = V^2/2g + y + z \tag{1}$$

both E and z are measured upward from the datum, y is measured from the stream bed, $V^2/2g$ is measured upward from the water surface. It should be noted that: (a) For real fluid, the total energy E always decreases along the flow direction. A positive energy gradient means that the energy increases toward upstream. If l is positive toward upstream, $dE/dl = S_e$. (b) The channel slope is customarily defined as positive in the case where the bed elevation decreases in the downstream direction, that is, the slope is positive if the elevation of the channel bottom increases in the upstream direction, $dz/dl = S_0$. Differentiate E with respect to l

$$\frac{dE}{dl} = \frac{d}{dl}\left(\frac{V^2}{2g}\right) + \frac{dy}{dl} + \frac{dz}{dl} \tag{2}$$

therefore

$$S_e = \frac{d}{dl}\left(\frac{V^2}{2g}\right) + \frac{dy}{dl} + S_0 \tag{3}$$

If (2) is multiplied by minus one

$$\frac{dE}{d(-l)} = \frac{d}{d(-l)}\frac{V^2}{2g} + \frac{dy}{d(-l)} + \frac{dz}{d(-l)} \tag{4}$$

Eq. (3) becomes

$$-S_e = \frac{d}{d(-l)}\frac{V^2}{2g} + \frac{dy}{d(-l)} - S_0 \tag{5}$$

denoting $-l$ by x, we have

$$\frac{dE}{dx} = \frac{d}{dx}\frac{V^2}{2g} + \frac{dy}{dx} + \frac{dz}{dx} \tag{6}$$

$$-S_e = \frac{d}{dx}\frac{V^2}{2g} + \frac{dy}{dx} - S_0 \tag{7}$$

Eq. (7) is the dynamic equation for open channel flow. (According to *Iwagaki* [1953, p. 7], (7) is a special case of the dynamic equation for real fluid flow and should be derived directly from the Navier-Stokes equation.) It can be obtained directly by differentiating (1) with respect to x. Note that

$$\frac{dE}{dx} = -Se \text{ and } \frac{dz}{dx} = -S_0 \tag{8}$$

Eq. (8) means that both the total energy head and

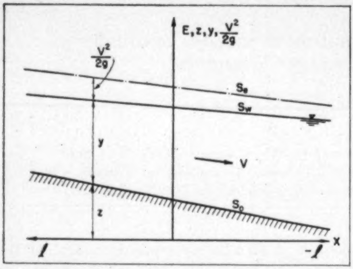

FIG. 1 – Definition sketch for gradually, non-uniform flow

the bottom elevation decrease in the flow direction.

If the channel is prismatic, the velocity head is only a function of the flow depth for a given discharge

$$\frac{d}{dx}\left(\frac{V^2}{2g}\right) = -\frac{Q^2}{gA^3}\frac{dA}{dx} = -\frac{Q^2B}{gA^3}\frac{dy}{dx} \tag{9}$$

Substituting (9) in (7) yields [*Rouse*, 1950, p. 610]

$$\frac{dy}{dx} = \frac{S_0 - S_e}{1 - Q^2B/gA^3} \tag{10}$$

where B is the water-surface width, A is the flow area, and Q is the total discharge.

If the channel is not prismatic, for a given discharge (steady flow) the velocity head is a function of the flow depth, and the distance x. For example, if the channel has a rectangular cross section, and its width B is a function of x, $A = By$

$$\frac{dA}{dx} = \frac{d}{dx}(By) = B\frac{d}{dx}y + \frac{dB}{dx}y \tag{11}$$

Substituting (11) in (7), and letting $Q^2/gB^2 = y_c^3$, yield [*Homma*, 1952, p. 158]

$$S_0 - S_e = \left[1 - \left(\frac{y_c}{y}\right)^3\right]\frac{dy}{dx} - \left(\frac{y_c}{y}\right)^3\frac{y}{B}\frac{dB}{dx} \tag{12}$$

Eq. (12) is the general equation for steady, gradually non-uniform flow in a rectangular channel of varying width.

Preliminary Report on the Alaskan Earthquake of April 7, 1958

T. NEIL DAVIS

Abstract—The Alaskan earthquake of 05h 30m April 7, 1958 (150° WMT) is the largest (Richter scale 7.0–7.5) of a series of shocks centered in an area near Huslia, Alaska. Severe breakage of lake and river ice and many ground cracks and mud flows occurred in the region of the field epicenter. A preliminary isoseismal map is presented.

The major Alaskan earthquake of 05h 30m April 7, 1958, 150° West Meridian Time, was felt sufficiently strong in Fairbanks to awaken many persons. The shock, of Richter magnitude 7.0 to 7.5, disaligned magnetic instruments of the U. S. Coast and Geodetic Survey Observatory at College, and was recorded on magnetic instruments at various field stations in Alaska. The intensity of the preliminary waves was sufficient to obscure the arrival of the secondary waves on the seismic equipment at the U. S. Coast and Geodetic Observatory at College. Through the use of S-P times of aftershocks, data from Sitka and other more distant stations it was possible to establish the epicenter as being about 250 mi northwest of Fairbanks.

On April 10, the author was flown to the area and was able to establish the field epicenter at a point near Huslia, Alaska, in the Koyukuk River basin. The position of the field epicenter is 155° 30′W, 65° 45′N. Severe lake-ice cracking, ground cracks, sinks, and extensive mud flows occurred in a zone approximately three miles wide by 35 miles long (Fig. 1) extending from the village of Huslia on the Koyukuk River in a northeasterly direction (azimuth 75° true) to a second point on the Koyukuk River. The southern part of the general area suffering the most severe surface effects consists of Quaternary alluvium and the northern part intersects a Tertiary volcanic ridge known as Bear Mountain.

At the time of the earthquake there was about two feet of snow on the ground and all lakes and rivers were frozen to a depth of approximately three feet. These conditions aided greatly in locating the area most affected by the shock.

The only nearby inhabitants of the region live in Huslia, a village of 150 people. The residents reported the duration of strong shaking to be approximately one minute, with horizontal motion SW-NE most noticeable. The shocks or preliminary earth noises at about 05h 30m 150° WMT awakened every adult in the village and caused some terror, particularly among the children. A moderate foreshock was felt by the villagers a week prior to the main shock at 05h 50m on March 31, 1958, 150° WMT and many aftershocks were also reported.

Actual monetary damage in Huslia was slight because most of the homes are of log construction and have no foundations. The only concrete found in the village was in piers underneath the one-story plywood school building. These were chipped by the main shock and some boards around the foundation of this building were knocked loose. Logs shook loose from window casings on two of the buildings and many of the houses received minor damage to roof structure. Case goods and other heavy objects moved for a distance of as much as twelve inches in the direction away from the epicenter.

Severe cracking of the river ice necessitated relocation of the river airstrip to a point where less cracking had occurred. Movement of the river ice created a pressure ridge of broken ice six feet in height along the southeast shore. Earth lurches on this bank left cracks in the soil up to forty inches wide and at least 20 ft deep.

Numerous earth lurches border small sloughs and ponds near Huslia. This area also contains a number of small mud flows and several sinks, some of which are 20 ft across and six feet deep. However, the most extensive damage is in an area between 10 and 30 mi northeast of Huslia. Many of the lakes in this region have large cracks in the ice with mud and vegetation ejected through them. Some lakes show severe shattering of the ice and in others no ice is visible. In these latter lakes, mud or muddy water appears to cover the ice completely. A few of the frozen streams had water or mud flowing in them after the shock.

The most striking result of the earthquake is the great volume of mud appearing on the surface at the field epicenter. Several of the larger mud flows cover an average area of one-quarter to one-half square mile with a mud depth of up to several

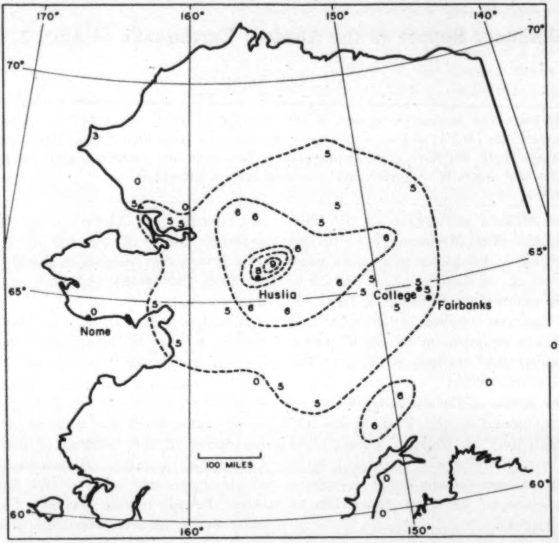

FIG. 1 – Preliminary isoseismal map of the earthquake of April 7, 1958

feet. One of the larger flows created a fanlike formation about 1000 ft long beyond which the mud flowed down a streambed for several miles. There are about ten flows of this size and hundreds of smaller ones. Associated with many of the flows are sinks located within a few hundred feet of the mud sources. The largest sink observed is 106 ft by 74 ft with a maximum depth of 13 ft.

As a part of the investigation of the earthquake a number of simplified questionnaires based on the U. S. Coast and Geodetic Survey earthquake questionnaire were sent to residents in Alaska. The response has been very good and a large amount of information is being obtained from the questionnaires and from voluntary letters. It is difficult to evaluate these data on the standard intensity scales because of the lack of a variety of construction near to the epicenter. Preliminary results indicate that the area over which the main shock was felt with an intensity of V or greater on the Modified Mercalli scale is in excess of 100,000 sq mi. As the shock occurred at a time when most people were asleep, the criterion of whether or not people were awakened was heavily used. The value V was assigned to a location if many or all persons were awakened by the shock. VI was assigned if most or all were awakened and if heavy objects were moved. At Huslia sand and mud ejection was the primary reason for the assignment of VIII. Preliminary intensity assignments at locations are shown on the accompanying map.

Subsequent to the earthquake vertical aerial photographs were taken which show the detail of the mud flows and ice cracking. One field party has visited the area and a second is planned. The results of these investigations will be published in a later paper.

Compressibility and Temperature of the Earth's Interior

FREDERICO MACHADO

Abstract—With a few assumptions regarding the constitution of the Earth's mantle and core, and using the values of pressure, density, and compressibility given by Bullen, the melting points at various depths were derived by Uffen's method. Assuming for the liquid core an adiabatic gradient, it seems that in the adopted Earth model the temperature of the lower mantle (below 800 km depth) is close to the melting point of the respective material and its strength is therefore much reduced. On the contrary the temperature of the upper mantle (depths 200 to 600 km) is considerably below the melting point and the material certainly has enough strength to permit the strain accumulation necessary to produce plutonic earthquakes.

Introduction—The temperatures of the interior of the Earth have attracted for a long time the attention of geophysicists. In recent years, *Uffen* [1952], *Jacobs* [1954], and *Verhoogen* [1954] have put forward important contributions to the problem. Their investigations assume, however, a homogeneous Earth's mantle, which appears to be a somewhat doubtful point [*Birch*, 1954]. In the present paper the non-homogeneity of the mantle will be also investigated, as well as its consequences regarding the temperature gradient within the Earth.

Effect of pressure on compressibility—*Bullen* [1953, pp. 220, 222] indicates the values of the bulk modulus $1/\chi$ and pressure P at various depths of the Earth (see Table 1), thus permitting to represent in Figure 1 the compressibility χ as a function of P. These adiabatic values of χ refer to the actual temperatures of mantle and core, where a temperature gradient certainly exists. Therefore the relations expressed in Figure 1 will also correspond to that gradient.

The variation of the compressibility is very regular within each of the regions B, D, and E (of Bullen's classification) and may be represented by the expression

$$\chi = a - bP + cP^2 \qquad (1)$$

where a, b, and c are coefficients which may depend on temperature. A least-squares adjustment gives for the coefficients the values indicated in Table 2, to which correspond the curves shown in Figure 1. The fit is extremely good.

For a homogeneous material at constant entropy the adiabatic compressibility is given by $\chi = (1/\rho)\, d\rho/dP$ where ρ is the density. By integration we obtain

$$\ln(\rho/\rho_0) = \int_0^P \chi\, dP \qquad (2)$$

from which ρ_0 (density at zero pressure) may be calculated.

We may use the compressibilities given by (1), but the values of ρ_0 must, in that case, correspond to the material that would exist at the level of zero pressure by imagining that the homogeneous layer and its temperature gradient were continued upward until that level.

Then by (1) and (2) we get

$$\ln(\rho/\rho_0) = aP - bP^2/2 + cP^3/3$$

Within each of the regions B, D, and E we can now compute the values ρ_0 corresponding to the values of ρ indicated in Table 1; the results are shown in Figure 2. Each of the three regions seems to be completely homogeneous but a considerable density difference exists between the upper and the lower mantle. This depends, however, on Bullen's assumptions for computing the densities, as was already pointed out by *Birch* [1952]. The values ρ_0 of each region correspond to a constant temperature which, as we shall see later, are incidentally not far from the respective melting point (about 1700 to 1900°K). Compressibilities at zero pressure, $\chi_0 = a$, evidently correspond to these same temperatures. Values of ρ_0 and χ_0 are given in Table 3.

It is almost generally accepted that the material in region B is some kind of dunite, and that the region E is composed of liquid meteoritic nickel-iron. The nature of the lower mantle (region D) is more uncertain. A reasonable fit to the value of the density is obtained if we assume a mixture of about equal parts of magnetite and olivine. At low pressure and low temperature χ is 0.5×10^{-12} cm²/dyne for magnetite, and 0.8×10^{-12} cm²/dyne for olivine [*Birch* and others, 1954]. We do not know however if at high temperature the compressibility of the mixture of the two minerals would decrease to only 0.4 × 10^{-12} cm^2/dyne (value in region D).

Another possibility, suggested by the stony meteorites, would be a rock formed by three parts olivine and one part meteoritic iron, but we know also too little about the behavior of such a mixture. It is interesting to remember that large concentrations of both magnetite and iron occur in a few places as segregations of igneous rocks [*Daly*, 1933, pp. 410, 559].

Melting point gradients—According to *Uffen* [1952] the melting point (in degrees Kelvin) of a solid may be computed by the simple formula

$$\tau = C/\rho\chi \tag{3}$$

where C is constant for a given material.

TABLE 1 – *Bullen's values of pressure, compressibility, and density*

Depth	P	χ	ρ
km	10^{12} dynes/cm²	10^{-12} cm²/dyne	gm/cm³
33	0.009	0.862	3.32
100	0.031	0.806	3.38
200	0.065	0.725	3.47
300	0.100	0.649	3.55
413	0.141	0.578	3.64
600	0.213	0.389	4.13
800	0.300	0.313	4.49
1000	0.392	0.279	4.68
1400	0.58	0.238	4.92
1800	0.78	0.205	5.14
2200	0.99	0.180	5.34
2600	1.20	0.161	5.54
2898	1.37	0.154	5.69
2898		0.161	9.4
3000	1.47	0.154	9.6
3500	1.95	0.123	10.2
4000	2.40	0.103	10.7
4500	2.81	0.090	11.2
4982	3.17	0.079	11.5

The formula is partly based on Lindemann's theory of fusion [*Richtmyer* and *Kennard*, 1947, p. 430], according to which ρ and χ (or the related frequency) must correspond to the solid phase at melting temperature. The actual temperature at the inner core boundary (depth about 5000 km) probably coincides with the melting point [*Jacobs*, 1956]. Near the base of the crust the melting point must also be reached because magmas are produced there; *Gutenberg* [1948] obtained evidence that this fact probably occurs at a depth of 80 to 100 km.

It is then reasonable to assume that between the depths of 100 and 5000 km the actual temperatures are never so far from the melting points that we might not compute these with Bullen's values of ρ and χ (and also with the values at zero pressure of Table 3).

From (3) we derive

$$\tau/\tau_0 = \rho_0\chi_0/\rho\chi \tag{4}$$

the subscript zero referring to the values at zero pressure.

The application of (4) to the upper core meets with some difficulty because there the material is assumed to be in the liquid state. As we are however calculating ratios of quantities affected by similar errors, the final result will not be much modified. In Table 4 we give the ratios τ/τ_0 computed by (4) for regions B, D, and E.

We shall now assume, for our Earth model, the following melting temperatures at zero pressure [derived from *Birch* and others, 1954; *Daly*, 1933]:

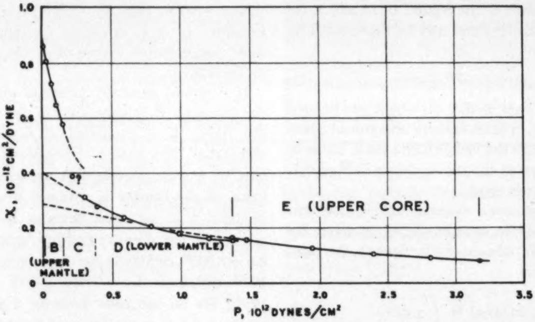

FIG. 1 – Compressibility as a function of pressure

TABLE 2 - *Coefficients of* $\chi = a - bP + cP^2$

Region	a	b	c
	10^{-12} cm²/dyne	10^{-24} cm⁴/dyne²	10^{-36} cm⁶/dyne³
B (upper mantle)	0.887	2.76	4.00
D (lower mantle)	0.400	0.344	0.120
E (upper core)	0.287	0.113	0.0150

4500	1.99	3.5
4982	2.21	3.9

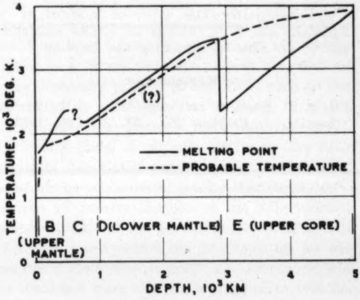

FIG. 3 - Melting points and probable temperatures within the assumed Earth model

upper mantle (dunite), 1670°K; lower mantle (magnetite?), 1860°K(?); upper core (nickel-iron), 1770°K. (For the composition of the lower mantle we assumed a mixture of minerals where the melting point of magnetite is probably representative of the melting point of the mixture.) The corresponding values of τ at the various depths are also given in Table 4.

At the boundary of the inner core the melting temperature is about 3900°K, which is close to that obtained by *Simon* [1953], but considerably below the values of *Gilvarry* [1956]. However, the same agreement with Simon's formula is not verified for the higher levels of the core, probably because there the temperature is a little too far from the melting point.

For the lower mantle and core the melting gradient (Fig. 3) has the general form suggested by *Jacobs* [1954]; but for the transition (region C) between the upper and lower mantle the decrease of the melting point (with increasing depth) is rather different from the usually assumed gradient.

Approximate temperatures—We have seen that temperatures at the depths of 100 and 5000 km may be assumed to coincide with the melting points for which we found 1800 and 3900°K, respectively. Transfer of heat in the liquid core (between the 5000 km level and the core boundary) must be partly due to convection, and therefore the adiabatic temperature gradient probably will be found in region E. A mean value of this gradient is 0.2 deg/km [*Jacobs*, 1956] and the temperature decrease, from 5000 to 2900 km, may be estimated at about 400°K, putting the temperature of the bottom of the mantle at 3500°K, which is a value of the order of magnitude of the melting point computed in the last chapter.

From the transmission of seismic waves we know that the mantle is in a solid condition, and then the temperature through the lower mantle must be somewhat below (but probably close to) the respective melting point (Fig. 3). At a depth of about 800 km a transition in the melting gradient is met and the material above this level appears to be a few hundred degrees below the melting point, until of course the depth of 100 km is approached.

Production of earthquakes depends on strain accumulation which is only possible if the material involved has enough strength. When the temperature of a solid is near the melting point, its strength is certainly very low, which is a condition found in the lower mantle of the assumed Earth model. This would explain why plutonic earthquakes only occur in regions B and C, no foci having been located at depths below 800 km.

The Nature of the Mohorovicic Discontinuity

J. F. LOVERING

Abstract—New evidence for the composition of the silicate mantle of the primary meteorite body suggests that a considerable portion of the Earth's upper mantle may well be composed of silicate material of basaltic composition. Consequently the Mohorovicic discontinuity may not separate basaltic crustal material from ultrabasic upper-mantle material but rather mark a zone in which basaltic material is transforming into a high-pressure modification possibly represented by the rock-type eclogite. Estimates of the temperatures and pressures at the average levels of the Mohorovicic discontinuity under oceans and continents give two points on the 'equilibrium line' for the transformation basalt → eclogite which is roughly given by the relationship $p = 21.8\theta - 488$ (p in bars, θ in °C). The geophysical consequences of this hypothesis are far reaching. It removes difficulties arising from the observed equivalence of oceanic and continental heat flows, provides satisfactory 'parent magma' from which the granitic and basaltic zones in the crust have differentiated, and suggests a mechanism for elevating or depressing regions of the Earth's surface simply by increasing or decreasing the temperature at the level of the Mohorovicic discontinuity beneath that region.

Introduction—The existence and depth of the Mohorovicic discontinuity which marks the accepted boundary between the Earth's crust and mantle are no longer in doubt. In general, geophysicists would agree that the composition of the 'continental' crustal rock is essentially that of an igneous rock intermediate between granite (or the even more petrologically likely rock-type granodiorite) and basalt while 'oceanic' crustal rocks are more likely to be basaltic in composition. On the other hand there is little agreement on the nature of the material which underlies the crust in both oceanic and continental regions.

Most workers have followed the concept that a change in chemical composition of the materials above and below the Mohorovicic discontinuity is the cause of the seismic discontinuity. For example in a recent review *Jacobs* [1956] concluded that peridotite best met the geophysical and geochemical requirements for the rock of the upper mantle while other authors, including *Bullen* [1953], have suggested dunite. From the literature it is obvious that these suggestions have been strongly influenced by Earth models proposed by *Washington* [1925] and others which were based on the then-existing knowledge of the compositions of the stony (that is, silicate rich) meteorites.

Evidence for a phase transformation—It is generally accepted that stony meteorites may be regarded as samples of the silicate mantle of the parent meteorite body and, by analogy, as samples of the chemical types of rock which probably make up the Earth's mantle. Previous models for the composition of the mantle of the parent meteorite body and the Earth have been confused by including the chondritic and polymict brecciated stony meteorites [for example, *Washington*, 1925; *Daly*, 1943; *Brown* and *Patterson*, 1948]. These are essentially tuffaceous and brecciated bodies which could not have formed by any process of differentiation of a silicate melt but only as the result of some secondary process [*Wahl*, 1952] such as the accumulation of fragments resulting from the disruption of the primary body [*Lovering*, 1957]. Excluding these, it appears that only the non-polymict brecciated stony meteorites (that is, most of the achondrites) can be legitimately considered as primary samples of the differentiated silicate mantle of the parent meteorite body. In this way a new model can be drawn up for the mantle of the meteorite body. This new model will be discussed more fully in another place but the main features can be summarized as:

(1) A basal zone, situated just above the metal core, composed of dunitic material. The observed abundances of meteorites which formed in this basal zone would indicate that this zone comprised about five per cent by volume of the silicate mantle.

(2) An intermediate zone (about 35 pct) situated above the basal zone in which peridotitic and pyroxenitic achondrites formed.

(3) An outer zone (about 60 pct) in which basaltic or eucritic achondrites, with compositions very similar to terrestrial basalts and norites, have formed.

In Table 1 the mean composition of these eucritic achondrites is compared with the mean compositions of terrestrial norites (which form the parent

TABLE 1 - *Mean compositions of eclogites, olivine basalts, norites, and eucritic achondrites*

Compound	Mean eclogite 1	Mean olivine basalt 2	Mean norite 3	Mean eucritic achondrite 4

[b] All analyses recalculated to 100.00.

1. Mean of 34 ecolgite analyses [*Lapadu-Hargues*, 1953].

2. Mean of 116 olivine basalt analyses [*Green* and *Poldervaart*, 1955].

3. Mean of published analyses of the noritic parent magmas from the Bushveld, Duluth, Sudbury, Belhelvie, Skaergaard, and New Zealand (North Island) differentiated intrusions.

4. Mean of 25 eucritic or basaltic achondrite analyses collected by *Urey* and *Craig* [1953].

magmas of certain differentiated and layered intrusions found near the Earth's surface) and olivine basalts, both of which may well represent the material at the base of the crust. From these data it is at once obvious that if the greater part of the Earth's upper mantle was composed of material similar in composition to the eucritic achondrites (as was the upper mantle of the parent meteorite body) then such material would have a composition which is essentially identical with rocks such as basalts or norites which probably form major components of the lower regions of the Earth's crust. It is true that the analyses of basaltic achondrites collected by *Urey* and *Craig* [1953] show a certain variability in composition but this would be expected if the basaltic achondrites formed a layered complex, as *Hess* and *Henderson* [1949] have concluded from their studies on the Moore County eucrite.

There is, then, no evidence from the new meteorite analogy to indicate that the Mohorovicic discontinuity is due to a major change in chemical composition which would be required if ultrabasic rock formed the Earth's upper mantle.

If the possibility of a chemical change is removed, then the only other explanation capable of accounting for the known physical properties of the upper-mantle rocks is that the Mohorovicic discontinuity represents a relatively narrow zone in which rocks of basaltic composition (including pyroxene granulites, somewhat higher-grade metamorphic equivalents of basalt) of mean density at zero pressure about 2.97 gm cm^{-3} are transforming into a high-pressure modification of basalt which, on *Bullen's* [1953] Earth model, has a density under the pressures operating in that region equal to that of olivine (that is, 3.32 gm cm^{-3}). It is suggested that the nature of this high-pressure modification of basalt is best represented by the dense rock-type eclogite (zero pressure density 3.35–3.6 gm cm^{-3}; mean about 3.4) on both petrological [*Turner* and *Verhoogen*, 1951] and geochemical grounds (see analyses of the average basalt and eclogite in Table 1).

The idea that eclogites might exist as a primary constituent of the Earth's mantle is by no means new, having been suggested previously by *Fermor* [1914] and again by *Holmes* [1927]. *Goldschmidt* [1922] proposed an Earth model in which eclogite formed a zone in the upper mantle between the levels 120 and 1000 km while *Birch* [1952], on evidence based on studies of the incompressibility, density, and other parameters of the mantle, suggested that depths to approximately 300 or 400 km in the mantle may be composed by eclogitic material. Recent experimental determinations of the pressure-temperature curve of the albite + nepheline → 2 jadeite transformation by *Robertson* and others [1957] would indicate that such a transformation which they have broadly compared with the basalt → eclogite transformation may well be taking place under the continents at the depths calculated for the Mohorovicic discontinuity.

The nature of the phase transformation—By means of the following simplified equations, *Turner* and *Verhoogen* [1951] have shown that olivine basalts and eclogites are chemically equivalent

$$\underset{\text{labradorite}}{[3\ Ca\ Al_2Si_2O_8 \ + \ 2\ Na\ Al\ Si_3\ O_8]} \ +$$

$$\underset{\text{olivine}}{3\ Mg_2Si\ O_4} \ +$$

$$\underset{\text{diopside}}{n\ Ca\ Mg\ (SiO_3)_2} \ \rightarrow \ \underset{\text{garnet}}{3\ Ca\ Mg_2Al_2\ (SiO_4)_3} \ +$$

$$\underset{\text{omphacite}}{[2\ Na\ Al\ (Si\ O_3)_2 \ + \ n\ Ca\ Mg\ (Si\ O_3)_2]} \ +$$

$$\underset{\text{quartz}}{2\ Si\ O_2}$$

By replacing labradorite by bytownite and olivine + diopside by pigeonite, a similar equation may be written to show how the eucritic achondrites (for example, the Moore County eucrite, see

Hess and *Henderson* [1949]) are also chemically equivalent to eclogites

$$\underset{\text{bytownite}}{[4\ \mathrm{Ca\ Al_2Si_2O_8} \ + \ \mathrm{Na\ Al\ Si_3\ O_8}]} \ +$$

$$\underset{\text{pigeonite}}{[8\ \mathrm{Mg\ Si\ O_3} \ + \ n\ \mathrm{Ca\ Mg(SiO_3)_2}]} \ \rightarrow$$

$$\underset{\text{garnet}}{4\ \mathrm{Ca\ Mg_2Al_2(Si\ O_4)_3}} \ +$$

$$\underset{\text{omphacite}}{[\mathrm{NaAl\ (SiO_3)_2} \ + \ n\ \mathrm{Ca\ Mg(Si\ O_3)_2}]} \ +$$

$$\underset{\text{quartz}}{5\ \mathrm{Si\ O_2}}$$

From these simplified equations it does not seem unreasonable to suggest that the course of the basalt → eclogite transformation involves the nucleation of new pyroxene (that is, omphacite) and garnet phases as a result of solid-state diffusion. If this is the case, then the speed of the reaction is very dependent on the diffusion constant of the ions involved in the transforming system and thus to a large extent upon the temperature at which the transformation is taking place. However there is ample evidence from their petrology to indicate that eclogites are extremely unstable rocks in the Earth's crust and that reactions which bring about their transformation to less-dense rock types can proceed in geologically short times even at the relatively low temperatures which generally exist in the outermost zones of the crust. Under anhydrous conditions eclogites on the Earth's surface often show evidence of at least partial transformation to basaltic-type rocks with omphacite being replaced by a myrmekite-like intergrowth of diopside and plagioclase. In the hydrous environment which is more common in near surface regions of the crust complete gradation may be traced from unaltered eclogite, through eclogite amphibolites containing relict garnet and omphacite together with newly generated plagioclase and hornblende, to amphibolites of normal composition [*Turner* and *Verhoogen*, 1951]. The time involved in these retrogressive metamorphic reactions may be geologically short. For example eclogites in the Franciscan of California appear to show every stage of retrogressive metamorphism to glaucophane schists, indicating a maximum time for their alteration of the order of 10^8 years.

Estimated pressure-temperature curve for the basalt → eclogite transformation—If the Mohorovicic discontinuity marks the position of the basalt → eclogite transformation in the Earth's mantle, then a knowledge of the various depths to the Mohorovicic discontinuity and the corresponding temperatures at these depths would enable an estimate to be made of the pressure-temperature curve for the transformation. For example the depth to the Mohorovicic discontinuity under the oceans is considerably less than the depth under the continents so that if the temperatures at each of these depths is calculated, then two points on the pressure-temperature curve are given. The temperature distribution in the crust is by no means well known and a recent summary by *Birch* [1955] has indicated how four widely varying distributions can arise depending on the particular set of more-or-less plausible assumptions which is used in the calculations.

For the present purpose typical values of the temperature at the Mohorovicic discontinuity under the oceans and under the continents are required and these are derived *ab initio* from the surface heat flux and an assumed typical distribution of radioactivity. The temperatures calculated are of the same order as those of *Birch's* [1955] curve B in the crust, but in the upper part of the mantle very different values would be obtained on the present assumptions.

In principle, the pressure and temperature at any depth below a point on the Earth's surface can be calculated from a knowledge of the heat flux at the point and the properties of the material below it. The heat flux may be regarded as a fundamental geophysical quantity which will ultimately be mapped at all points of the Earth's surface: at the present time the average value under the oceans is not significantly different from the average value of 1.2×10^{-6} cal cm^{-2} sec^{-1} on the land [*Bullard* and others, 1956] and, for simplicity and ease of comparison, this value will be used in both cases.

On the present hypothesis, the crust below the oceans is assumed to consist of typical olivine basalt with known thermal conductivity K_0, density ρ_0, and rate of radioactive heat generation per unit mass A_0, all constant, so that the temperature may be estimated fairly definitely. If the heat flux at the ocean bottom is H and the temperature there is 0°C, the temperature θ at depth x below the ocean floor is given by

$$\theta = (Hx - \tfrac{1}{2}\rho_0 A_0 x^2)/K_0 \cdots \qquad (1)$$

Using the typical values $H = 1.2 \times 10^{-6}$ cal cm^{-2} sec^{-1} [*Bullard* and others, 1956], $A_0 = 3.5 \times 10^{-14}$ cal gm^{-1} sec^{-1} [*Jacobs*, 1956], $K_0 = 0.0057$ cal cm^{-2} sec^{-1} (°C cm^{-1}) (the mean of all values in

Birch and others [1942]), $\rho_0 = 2.97$, values of the temperature at any depth can be found. A composite 'mean thickness' of the oceanic and continental crusts has been calculated from the most recent data of *Poldervaart* [1955] and *Ewing* and *Press* [1956]. Taking the average depth of the Mohorovicic discontinuity below the ocean floor to be 6 km, the temperature at this depth calculated from (1) is about 123°C, while the pressure at this depth for the case of an ocean of depth 5 km with 6 km of basalt of density 2.97 below it is about 2200 bars. This gives the point 0 on the curve I of Figure 1 which shows the temperature at any depth (expressed in terms of pressure) under the oceans as calculated from (1).

Temperatures under the continents are much more difficult to estimate because of the uncertainty in the depth of, and heat production in, the sialic layer. Taking as a model of the continental crust a layer of sialic material of depth x_1, thermal conductivity K_1, density ρ_1, and heat production per unit mass A_1 lying on a substratum of basalt of conductivity K_0, density ρ_0 and heat production A_0, the temperature θ at depth x is given by

$$\left.\begin{aligned} \theta &= (H - \tfrac{1}{2} A_1 \rho_1 x)\, x/K_1\,, \quad 0 < x < x_1 \\ \theta &= \frac{(2H - \rho_1 A_1 x_1)x_1}{2K_1} \\ &\qquad + \frac{(H - \rho_1 A_1 x_1)(x - x_1)}{K_0} \\ &\qquad\qquad - \frac{\rho_0 A_0 (x - x_1)^2}{2K_0}, \quad x > x_1 \end{aligned}\right\} \qquad (2)$$

where the temperature at the surface ($x = 0$) is taken to be 0°C and the heat flux to be H. Assuming the sialic layer to consist of 10 km [*Gutenberg*, 1951] of granodioritic material [after *Poldervaart*, 1955] with the typical values $\rho_1 = 2.76$, $A_1 = 1.2 \times 10^{-13}$ cal gm^{-1} sec^{-1} [*Jacobs*, 1956], $K_1 = 0.0065$ (mean of values in *Birch* and others [1942]) and with the values for basalt as used previously, the temperature at a depth of 35 km (a reasonable value for the depth of the Mohorovicic discontinuity under the continents), is found to be 480°C, the pressure there being 10,000 bars. This gives the point C on the curve II of Figure 1 which shows the temperature at any depth, (that is, pressure) under the continents as calculated from (2).

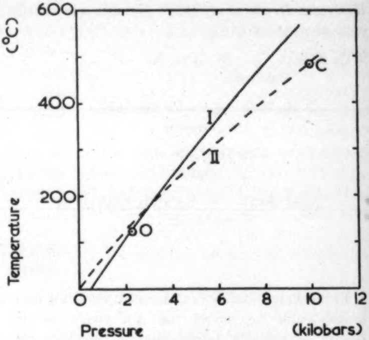

FIG. 1 – Distribution of temperature and pressure under the average ocean (I) and continent (II)

It appears from the relationship of curves I and II of Figure 1 that the variation of temperature with depth (or pressure) is determined more by the assumed value of the surface heat flux than by any other quantity. Small variations in the parameters will affect the relative positions of the curves (and in particular whether they cross as in Figure 1 and the place at which this occurs) but they will not alter the positions of the points 0 and C in order of magnitude and it may be assumed that $p - \theta$ curve for the reaction basalt → eclogite lies in the neighbourhood of the line 0C. This gives in order of magnitude

$$\frac{d\theta}{dp} = 0.046 \text{ where } \theta = 300°\text{C}$$

and since the change in volume is -0.046 cm^3 gm^{-1}, the Clausius-Clapeyron relation gives ΔH $= -14$ cal gm^{-1} which is of reasonable order of magnitude. Since $d\theta/dp$ is generally a function of θ or of p, the phase boundaries show some curvature but for the purposes of this study $d\theta/dp$ will be taken to be a straight line 0C given by the relation $p = 21.8\theta - 488$ where p is the pressure in bars and θ is the temperature in degrees centigrade (see Fig. 2).

It should be remarked that the above calculation has used values typical of oceanic and continental conditions in an attempt to establish approximately the position of the $p - \theta$ curve. If this latter is regarded as being known accurately, the depth of the Mohorovicic discontinuity at any point would be determined by the heat flux and the nature of the crustal material at the point in question; in particular under the oceans it would be determined almost entirely by the heat flux.

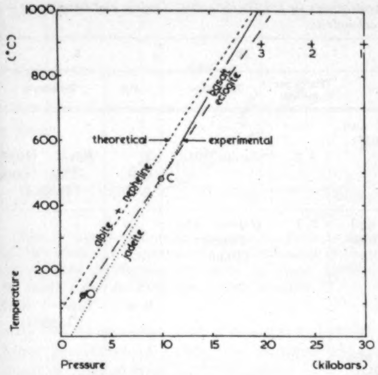

FIG. 2 – Estimated pressure-temperature curve for the transformation basalt → eclogite compared with theoretical [after *Kelley* and others, 1953] and experimental [after *Robertson* and others, 1957] equilibrium curves for the reaction albite + nepheline → 2 jadeite

This argument is independent of the source of the heat coming from below, that is, where it is provided by conduction or convection, provided that steady conditions prevail.

The temperature of 123°C derived above for the temperature at the Mohorovicic discontinuity under the oceans is suprisingly low and at first sight would seem to be too low for the basalt → ecologite reaction to proceed at a reasonable speed. However it has been pointed out earlier that eclogites show considerable evidence of being reactive at the relatively low temperatures which operate near the Earth's surface in times which are geologically small. It is, then, not unreasonable to expect the basalt → eclogite transformation to be proceeding at the oceanic Mohorovicic discontinuity level in geologically reasonable times.

Robertson and others [1957] have recently determined experimentally the equilibrium line for the reaction albite + nepheline → 2 jadeite, while *Kelley* and others [1953] had previously determined a theoretical line for the reaction from thermochemical data (see Fig. 2). The pyroxene 'omphacite' in eclogites is not pure jadeite ($NaAlSi_2O_6$) but may be regarded as a diopside-jadeite solid solution with some additional Al replacing Ca. *Robertson* and others [1957] have concluded that the pressure needed to form an omphacite pyroxene is probably less than that needed to form jadeite but in general it is to be expected that the equilibrium line for the formation of jadeite from albite and nepheline should be fairly close to that estimated for the formation of ecologite from basalt. From Figure 2 it is evident that this may well be the case.

The points given by *Coes* [1955] as representing the 'best conditions' for the formation of pyrope, pyrope + 5pct almandite, and grossularite are indicated in Figure 2 by the crosses 1, 2, and 3 respectively. The pyrope, and to some extent the pyrope + 5pct almandite points lie well within the eclogite field but grossularite is very close to the basalt → eclogite boundary. Now the garnet of eclogites is not a pure pyrope but is actually a lime-bearing almandite-pyrope with 25–70 pct pyrope and 12–40 pct grossularite [*Turner* and *Verhoogen*, 1951]. From Coes' data the equilibrium pressure of eclogite garnet at 900°C might be expected to lie between points 2 and 3 in Figure 2 and, as a result, lie less than five kilobars above the equilibrium pressure at 900°C for the basalt → eclogite reaction. On the basis of their experimental data *Robertson* and others [1957] found that Coes' 'best condition' point for jadeite at 900°C was about two kilobars above the equilibrium pressure at that temperature.

It should be pointed out that the use of a single line in the $p - \theta$ diagram to separate the stability fields of basaltic (that is, pyroxene and plagioclase) and eclogitic (that is, omphacite pyroxene and garnet) rocks is a simplification of the true situation since it is not yet established how many components are concerned even though it does seem likely that there are only two main phases involved on each side.

Geophysical implications—The suggestion that the materials above and below the Mohorovicic discontinuity have essentially the same composition, being separated by a phase change, has consequences of great geophysical importance. Firstly, it implies that the concentration of radioactive elements, and hence the heat production per unit mass, should be the same throughout the extent of the material in both phases, a point which was made previously for the calculation of temperature-depth curves in the oceanic and continental crust.

This immediately removes the well-known difficulty involved in finding a source for the heat flux from the oceans which is known to be of the same order of magnitude as that from the continents. If the material below the Mohorovicic discontinuity is assumed to be ultrabasic in charac-

ter with the low radiogenic heat production of known ultrabasic rocks it is extremely difficult to account for this equality and other explanations, such as convection in the mantle, have been invoked [*Bullard* and others, 1956]. On the other hand, if the material below the Mohorovicic discontinuity has a composition similar to that of a basaltic rock with a similar high rate of radiogenic heat production (of the order of 3.5×10^{-14} cal gm^{-1} sec^{-1}), it appears that the whole heat flux of 1.2×10^{-6} cal cm^{-2} sec^{-1} could be produced by a layer of such material about 100 km in thickness. If the concentration of radioactive elements diminishes even only slightly with depth, as seems geochemically likely, it would be possible that this material extended to a depth of 200–300 km implying that the region B of the mantle might well be composed of such material (that is, eclogite).

The few data available on the concentration of radioactive elements in eclogites and achondritic meteorites have been summarised in Table 2. *Holmes* and *Paneth* [1936] determined the uranium and thorium contents of a number of inclusions in the South African diamond pipes including three eclogites and three zircon crystals. *Smales* [1952], using a radioactivation technique, redetermined the uranium contents of the same three zircon crystals and found values considerably lower than they had reported. There is then good reason to suppose that the uranium contents of the three eclogites reported by *Holmes* and *Paneth* [1936] are also too high and in Table 2 their values have been corrected by Smales' factor (average 0.43 calculated from the zircon analyses) to bring them into line with his presumably more accurate analytical technique. It is then apparent that the uranium, thorium, and potassium contents of basalts and eclogites are sufficiently alike for eclogitic rocks to be a suitable material for the upper part of the Earth's mantle.

From the meteorite analogy it follows that the general level of concentration of radioactive elements in the basaltic or eucritic achondrites should be similar to that of their suggested terrestrial equivalents (that is, basalts and eclogites). The data in Table 2 indicate that the levels are similar although the absolute values are somewhat lower. Since many of these achondrites have presumably formed at greater relative depths in their parent body than those basalts and eclogites available for analysis have in the Earth, these achondrites

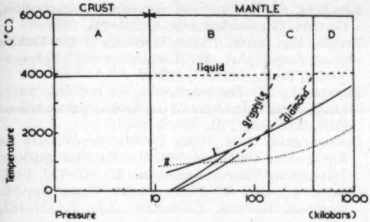

FIG. 3 – The graphite-diamond stability fields in the Earth's crust and upper mantle from estimates of the temperature distribution according to *Jacobs* [1956] for curve I and to *Verhoogen* [1956] for curve II

may well be expected to have retained a slightly lower proportion of radioactive elements as a result of more advanced differentiation.

The occurrence of certain accessory minerals in terrestrial eclogites may be used to estimate the depths in the Earth's mantle from which eclogitic rocks have apparently been derived. It is well known that certain eclogites contain diamonds so that the minimum depth in the mantle from which such eclogites could have come may be calculated by the minimum depth in the mantle at which diamond becomes stable. The equilibrium curve for the graphite → diamond transformation is fairly well established even up to temperatures of around 4000°C as a result of the experimental work of *Bundy* and others [1955] and is given in Figure 3. Also included in this figure are two estimates of the temperature distribution in the upper mantle recently proposed by *Verhoogen* [1956] and *Jacobs* [1956]. With increasing depth these estimates are widely variant but in the region of the upper mantle agreement is reasonably satisfactory. From Figure 3 it is apparent that diamond becomes stable in the mantle at depths of from 130–190 km so that eclogites containing diamond must have formed at least at these depths which are well within Region B. Other eclogites (that is, those containing quartz as a primary constituent) must have formed at considerably shallower depths since from what is known about the quartz → coesite transformation, quartz cannot exist at depths greater than 60–100 km [*MacDonald*, 1956].

A second consequence, and one with important geochemical and petrological implications, is that the 'primary magma' from which the various chemical rock types in the mantle have differentiated must have a composition closer to basic rather than to ultrabasic silicate material (as had been thought to be the case previously). It has long been a problem to derive the granitic and basaltic components of the Earth's crust by the differentiation of the ultrabasic material which was thought to make up the material in the Earth's mantle [*Voytkevich*, 1955]. If a good deal of the upper mantle is composed of rock of basaltic composition, as follows from this work, then this problem no longer exists.

A third consequence, and probably the most important one, is the mechanism which this concept for the nature of the Mohorovicic discontinuity provides for certain regions of the Earth's crust to be raised relative to adjacent static regions simply by increasing the temperature at the Mohorovicic discontinuity under the mobile tract. Such a temperature rise at the base of the crust would follow the final stage of a convective overturn of the type envisaged by *Griggs* [1939] as operating in the mantle. The temperature at the discontinuity will rise and the position of the discontinuity will become unstable and should, as a consequence of Figure 2, sink to greater depths. The eclogitic material which originally existed between the original and final levels of the discontinuity will transform to basaltic material with a volume increase of something like 15 pct. It is the volume increase which then provides the mechanisms for raising the overlying crustal column relative to adjacent regions under which the Mohorovicic discontinuity has been unaffected. Similarly a decrease in temperature at the base of the crust would cause a depression at the Earth's surface above this region. It is immediately obvious that this process has far-reaching geophysical implications. For instance the existence of the so-called 'roots' under uplifted mountain ranges, as well as the uplifting mechanism itself, follows as a direct result of an assumed temperature rise at the base of the crust under these regions. A more detailed discussion of these and other geophysical implications will appear in another place.

Conclusions—By analogy with a new model for the mantle of the primary meteorite body, the depth to which silicate material of basaltic composition should exist in the Earth must be increased far beyond the currently accepted limit which is taken to be the Mohorovicic discontinuity. Consequently the Mohorovicic discontinuity itself may not mark a chemical change from basaltic material in the lower crust to ultrabasic material in the upper mantle but rather a zone in which basalt is transforming to a high-pressure modification, most likely represented by the dense rock-type eclogite. Since the levels of the Mohorovicic discontinuity under oceans and continents are different then calculations of the temperatures and pressures at each of these depths gives two points on the equilibrium curve for the basalt → eclogite transformation which appears to be a line roughly given by the relation $p = 21.8\theta - 488$. The 'equilibrium line' is in general agreement with the latest experimental data for the formation of the pyroxenes and garnets found in eclogites. The geophysical consequences of a phase change at the Mohorovicic discontinuity are far-reaching and include the predicted equivalence of oceanic and continental heat flows, a satisfactory 'parent magma' from which the granitic and basaltic crustal zones could have differentiated as well as providing a mechanism by which certain regions of the Earth's surface can be raised vertically simply by causing an increase in temperature at the base of the crust beneath that region which results in the Mohorovicic discontinuity being displaced downwards and a certain amount of high-density material transforming into a less-dense modification with a corresponding volume increase.

Acknowledgments—J. C. Jaeger very kindly made the new set of calculations for the distribution of temperature beneath the oceanic and continental regions and has further aided this work by his critical interest and discussion.

A^{40}/K^{40} Age of Gneiss from McMurdo Sound, Antarctica

S. S. GOLDICH, A. O. NIER, AND A. L. WASHBURN

Abstract—Biotite from paragneiss of Gneiss Point, McMurdo Sound, Antarctica is dated at 520 m y by the A^{40}/K^{40} method. Metamorphism of Precambrian sediments at the close of Precambrian or in Cambrian time is indicated, but additional work is needed.

Introduction—Paragneiss bedrock from Gneiss Point on the west side of McMurdo Sound, Antarctica (Fig. 1) is dated at 520 million years by A^{40}/K^{40} analysis of biotite separated from the gneiss. The sample was collected by R. P. Goldthwait and A. L. Washburn during a short reconnaissance to Gneiss Point in December, 1957, in the course of investigations sponsored by the U. S. National Committee, International Geophysical Year.

The dated specimen (57-12-3d) was collected from the crest of the most prominent hill on Gneiss Point (approximately, lat. 77°25′S, long. 163°43′ E). West of this locality there is a belt of coarsely crystalline white marble trending roughly north-south across the point, and other rock types occur west of the marble belt. According to *Smith* and *Debenham* [1921, p. 144] the metamorphic rocks along the coast in this vicinity "....comprise a considerable thickness of schists and crystalline limestones, probably associated with pyroxene-granulites; and represent metamorphosed argillaceous, calcareous, and dolomitic sediments. In addition to this sedimentary series there is an intrusion, probably quite considerable, of biotite-hornblende gneiss and some amphibolites and hornblende-schists probably representing altered dyke-rocks."

Description of sample—Specimen 57-12-3d is a dark-gray, medium-grained gneiss with well-developed compositional banding. Biotite is abundant in the mafic layers. The light-colored feldspar-quartz bands are considerably coarser in grain than the dark bands. The gneiss undoubtedly is of sedimentary origin, and the sample cannot be considered to be representative of the bedrock of the vicinity; however, a point-count analysis of a thin section gives the following mode: andesine (An_{35}), 38 pct; biotite, 30; hornblende, 20; augite, 6; and quartz, 6.

Orthoclase (one per cent or less) is included with the andesine, because it is largely in antiperthite. Accessory minerals, probably less than one per cent, include apatite, sphene, and zircon. Pleochroic halos around these minerals are well developed in the biotite. Some of the hornblende developed at expense of augite as is indicated by irregular relicts of pyroxene, and there is some sericite in the andesine. There is a trace of chlorite formed from the biotite, but the rock is remarkably fresh and unaltered. The sample is classified as biotite-hornblende-andesine paragneiss and indicates metamorphism of rather high-grade amphibolite facies.

Biotite was separated from crushed material (40–60 mesh) with a Franz Isodynamic separator and was estimated to be 95 pct or more of the final separate, the principal impurity being hornblende. Determinations in the Rock Analysis Laboratory gave 8.33 and 0.06 pct for K_2O and Rb_2O, respectively. Two determinations of A^{40} gave 1.57×10^{-4} and 1.58×10^{-4} cc STP/gm, and the A^{40}/K^{40} ratio is 0.0333. The empirical values of 0.557×10^{-10}/yr for λ_e and 4.72×10^{-10}/yr for λ_β [Wetherill and others, 1956] give an age of 520 m y.

Discussion—The stratigraphy and structure of Antarctica have been summarized recently by *Davies* [1956], and the petrology by *Stewart* [1956]. Gneiss Point is part of the East Antarctica Precambrian shield composed of metamorphic and intrusive crystalline rocks that are overlain by sedimentary series of lower Paleozoic and of Mesozoic age. The East Antarctica shield is set off from the folded Mesozoic and Cenozoic rocks of West Antarctica by a large fault or fault zone. The upthrown segment of this fault which extends from McMurdo Sound to the Weddell Sea, skirting the South Pole, has been called the Great Antarctica Horst and constitutes one of the major tectonic features of Antarctica [*David* and *Priestley*, 1914; *Fairbridge*, 1952].

Gneiss Point is situated on the great fault zone and also is in close proximity to the volcanic islands of the Ross Sea of which Ross Island is active. For these reasons geologic interpretation of the 520 m y age must be cautious. Specifically, the date supports the Precambrian age assigned by

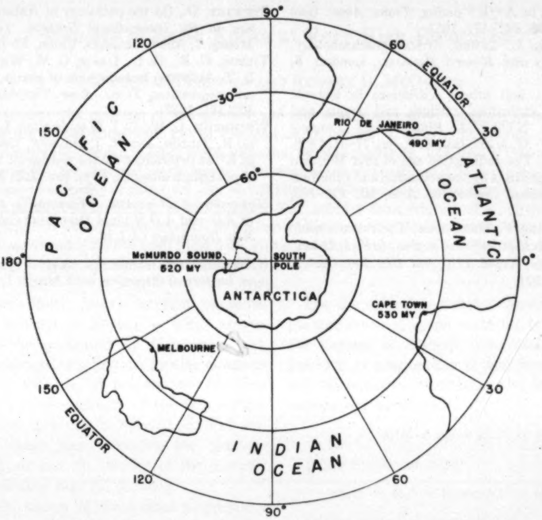

FIG. 1 – Sketch map showing location of dated sample from McMurdo Sound, Antarctica

geologists to the East Antarctica shield. If it is assumed that the rocks of Gneiss Point have not been affected by events subsequent to the formation of the paragneiss, it can be said that the metamorphic rocks mark an orogeny essentially at the close of Precambrian or in Cambrian time. Some support for this hypothesis is afforded by by A^{40}/K^{40} dates of 490 m y [*Goldich*, *Baadsgaard*, and *Nier*, 1957] for biotite from gneiss at Rio de Janeiro, Brazil and of 530 m y for the Cape Town granite [*Tilton* and others, 1957]. These dates, as well as others [*Holmes* and *Cahen*, 1955] suggest the possibility that there was a period of orogeny and intrusion at the close of Precambrian time. Further work on rocks from Antarctica may help to establish or to eliminate the hypothesis, and certainly a major contribution to the geology of Antarctica can be made by dating rocks from the scattered and poorly known outcrops of this vast continent. That some ancient rocks will be found in Antarctica seems assured by radioactive ages in the range 2.6–2.8 b y that have been reported from Minas Gerais, Brazil [*Hurley* and others 1958], Western Australia [*Jeffery*, 1956] and Southern Rhodesia [*Holmes* and *Cahen*, 1955].

To the writers' knowledge the data here reported for the gneiss of McMurdo Sound is the first radioactive age determination of a rock from Antarctica.

Acknowledgments—We are indebted to Athelstan Spilhaus of the University of Minnesota for arranging transportation of samples from Antarctica and to our colleagues at Minnesota for help with the analytical work. The financial support of grants from the National Science Foundation and from the Graduate School of the University of Minnesota in support of the geochronology program at the University of Minnesota is gratefully acknowledged.

Density of Basic Rocks at Very High Pressures

DARRELL S. HUGHES AND ROBERT G. MCQUEEN

Abstract—The densities of two gabbros and one dunite have been measured at several pressures in the range from 150 to 750 kilobars (1 kilobar = 986.9 atmospheres). These pressures were attained in shock fronts generated by high explosives. The densities were computed from the observed shock waves. The dunite, initial density of 3.25 g/cc, was compressed to a density of about 4.9 g/cc at 720 kilobars. The gabbros, initial density 3.0 g/cc, were compressed to 5.0 g/cc at 750 kilobars. Both gabbros show evidence of a polymorphic transition at some pressure around 150 kilobars to a more dense, but less compressible phase. The agreement obtained from these data with a crust of dunite 400 kilometers thick underlain by a gabbroic rock with Bullen's Model A is very close.

Introduction—Shock fronts carrying pressures up to 1000 kilobars (1 kilobar = 986.9 atmospheres) may be generated by high explosives. High-speed photography permits precise measurements of the velocity of propagation of these shock fronts and the velocity of the free surface when the shock pressure is relieved at that surface. From these two velocities the pressure behind the front and the density of the material under this pressure may be deduced.

Theory—The theory of shock front propagation is very simple compared to the theory of large amplitude wave motion. The basic equations will be reviewed briefly following the notation and development of *Courant* and *Friedrichs* [1948, pp 107–160]. Any material in which the sound speed increases as the material is compressed will transmit compressive shock fronts. Qualitatively this is easy to understand since if two compressive wave fronts are traveling in the same direction the second wave is moving through material already compressed by the first. It is therefore traveling faster and will overtake the first. Any large amplitude disturbance will then become a shock if dissipation processes, such as viscosity or heat conduction, do not remove too much energy.

Figure 1 illustrates the propagation of a shock front through one material and into a second material the other face of which is free, that is, bounded by gas at atmospheric pressure. In all materials and states ρ is the density, τ is the specific volume, u is the particle or material velocity, P is the pressure, and U is the shock front velocity. Even subscripts denote value of parameters before the arrival of the initial shock front, odd subscripts values after the first shock front, and primes the values after the second front.

Let the subscripts i and f denote values of the parameters in a given material before and after the passage of a shock front and let U be the velocity of propagation of the front. The fundamental equation connecting the initial and final values may be written

$$\rho_i(U - u_i) = \rho_f(U - u_f) \tag{1}$$

(conservation of mass)

$$\rho_i(U - u_i)^2 + P_i = \rho_f(U - u_f)^2 + P_f \tag{2}$$

(conservation of momentum)

$$\begin{aligned}\rho_i(u_i - U)(\tfrac{1}{2}u_i^2 + e_i) + P_iu_i \\ = \rho_f(u_f - U)(\tfrac{1}{2}u_f^2 + e_f) + P_fu_f\end{aligned} \tag{3}$$

(conservation of energy)

where e is the specific internal energy or energy per unit mass. Considering only the first two equations these contain seven parameters. The initial parameters ρ_i, u_i, P_i may be considered known; thus if any two of ρ_f, u_f; P_f, or U can be measured, the remaining ones can be computed. Practically, u_f and U are measured and ρ_f and P_f computed.

Introducing the specific volume $\tau = 1/\rho$ and taking u_i and P_i to be zero, Eqns. (1) and (2) reduce to

$$\tau_f = \tau_i(U - u_f)/U \tag{4}$$

$$P_f = \rho_iUu_f \tag{5}$$

Thus if U the shock velocity and u_f the particle velocity can be measured, the pressure and specific volume or density behind the shock front can be calculated. Several methods of making these measurements have been described [*Walsh*, 1955; *Minshall*, 1955; *Bancroft*, 1956].

The temperatures may be calculated by using certain thermodynamic identities [see, for ex-

ample, *Walsh*, 1955]. The final equation is

$$T_1 = T_0 \exp[b(\tau_0 - \tau_1)] + \exp(-b\tau_1)\int_{\tau_0}^{\tau_1} [f(\tau)\exp(b\tau)/C_\tau]_{\mathrm{Hug}}\, d\tau \quad (6)$$

where τ_0 is the initial specific volume
τ_1 is the final specific volume
T_0 is the initial absolute temperature
T_1 is the final absolute temperature
$b = (\partial P/\partial T)_\tau/C_\tau$
C_τ is the specific heat at constant volume
$f(\tau) = [(\tau_0 - \tau_1)(dP/d\tau) + P]/2$

The first term on the right of (6) is the temperature rise associated with an isentropic process; the second term is a correction that takes account of the fact that the shock process is nonisentropic.

The integral is taken over the Hugoniot curve in the $P - V$ plane. This curve is the locus of $P - V$ states that can be reached from some initial P_0V_0 state by shock processes. It differs very little from the adiabatic [*Courant* and *Friedrichs*, 1948, p. 138].

To obtain the pressure and density behind the shock, U and u_f must be determined. The shock velocity U can be measured directly but u_f cannot be measured directly. Referring to Figure 1*c*, u_{fs}, the free-surface velocity of the material, can be measured [*Walsh*, 1955; *Minshall*, 1955]. With very weak shocks (sonic waves) u_{fs} would be exactly $2u_i$. This is not true for shocks of the strength considered here; however it can be shown that [*Walsh*, 1955]

$$1 - \delta < u_{fs}/2u_f < 1 + \delta \quad (7)$$

where for most solids δ is of the order of 0.03; in particular this is true of the rocks considered here. Actually this error could be eliminated at

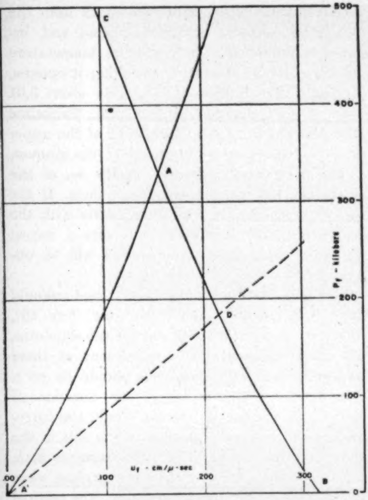

FIG. 2 – Hugoniot and adiabat for aluminum

the cost of rather elaborate computations, but it is unimportant in the present work.

Curve *A'A* in Figure 2 shows the experimentally determined relation between P_f and u_f in 24*S-T* aluminum. This curve can be derived by using (4) and (5), and the published data [*Walsh*, 1955, Table 2]. Consider point *A* in Figure 2; this represents a shock of about 330 kilobars into aluminum, the particle velocity is 0.16 cm/μsec, the shock velocity is about 0.76 cm/μsec. When this shock reaches a free surface the material at the surface which is under this pressure starts expanding. In doing so it follows the curve *AB*. If *CAB* is drawn as the mirror image of *AA'* with respect to the vertical through *A*, the particle velocity at *B* will be exactly twice the particle velocity at *A*. Actually the curve segment *AB* represents adiabatic states whereas the segment *AC* represents left-going shocks propagated into the aluminum after being shocked to state *A* by a right-going shock. It is not exactly a mirror image of the corresponding segment of *OA*, neither is it a continuation of the adiabatic from *A* to *B*, but it differs very little from either of these.

Consider the situation in Figure 1b; the shock in material *A* has reached the interface, a shock is being propagated into material *B*, and a reflected shock or rarefaction is traveling to the left in material *A*. Assume that material *A* is aluminum and that u_3, P_3, and U_3 are known and that U_1 in Figure 1b is measured. Now from (5)

$$P_1 = \rho_0 u_1 U_1 \qquad (9)$$

where P_1 and u_1 are at present unknown. Since u_3 and P_3 are known the point *A* on the aluminum curve is determined. Following the shock the aluminum must move along either *AC*, reflected shock, or along *AB*, reflected rarefaction into the aluminum. In (9), ρ_0 and U_1 are known; draw the straight line *OD* in Figure 2 with slope $\rho_0 U_1$, then the point *D* (in Figure 2) represents conditions at the interface between the aluminum and material *B* in Figure 1. As drawn a rarefaction is reflected into the aluminum. If *D* had fallen above *A* on *AC* a shock would have been reflected into the aluminum. Point *D* is then one point on the curve of the relationship of *P* to *u* of material *B*. By creating shocks of different strengths in the aluminum as many points as desired can be determined on the curve for material *B*, and then from (4) and (5) curves of the relationship of pressure to volume or pressure to density for material *B* can be drawn.

Anisotropy of the medium seems to be unimportant in this work. Even as anisotropic a material as zinc, in which the longitudinal wave velocities parallel and perpendicular to the *c*-axis are about 0.279 cm/μsec and 0.474 cm/μsec, shows no detectible shock wave anisotropy [*Walsh*, *Rice*, and *McQueen*, 1957].

Experimental method—The experimental method is the same as that described by *Walsh* and others [1955, 1957]. A cone of high explosive is built up of shells of high- and low-speed explosives in such a combination that when detonated at the apex the detonation front is accurately plane and perpendicular to the axis when it reaches the base of the cone. The base diameter is about ten inches, a block of uniform explosive ten inches in diameter and two to four inches thick is placed on the base of the cone, an aluminum plate about 12 × 12 inches is placed on the block. After detonation a plane shock wave travels through the aluminum plate. The strength of this shock will depend upon the composition and thickness of the high-explosive block. Since the shock in the aluminum is attenuated with distance of travel, the strength of shock reaching the front surface of the plate can be changed by using plates of different thickness.

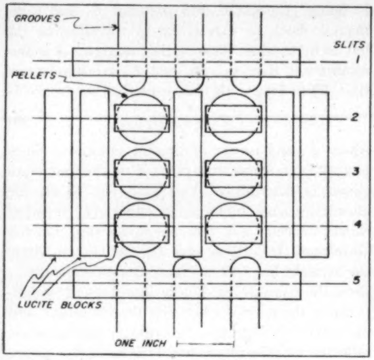

FIG. 3 – Layout of target plate

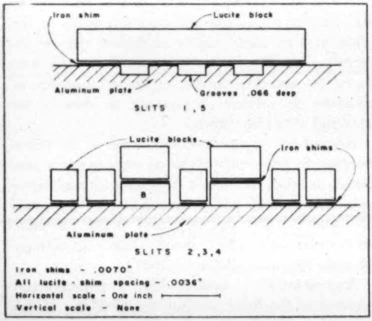

FIG. 4 – Cross section of target plate

Figure 3 shows one possible experimental layout on the front surface of the aluminum plate. Figure 4 shows cross sections at the relevant points. A thin aluminum plate with slits cut as shown in Figure 3 is placed over the assembly but is not shown in Figure 4.

In Figure 4 consider a shock wave being propagated upwards in the aluminum plate. The shock wave first hits the bottoms of the grooves which then move with a constant velocity u_{f_3} determined by the shock strength and the fact that the material is aluminum. The shock front itself hits the front of the aluminum plate and throws the iron shim upwards closing the gap between the iron shim and the lucite. This space is filled with argon gas which under the shock from the iron shim becomes brilliantly heated and intensely luminous. The intense temperature quickly destroys the lucite, rendering it opaque, so that a very brilliant flash of only about 0.01 μsec or less duration is produced. Sometime after the arrival of the shock front at the upper surface of the plate the bottoms of the grooves, which are moving with the velocity u_{f_3} of the aluminum, hit the iron shim over them. If the system is scanned by a rotating mirror with the axis of rotation parallel to the slits a record similar to that shown in Figure 5 will be obtained.

In Figure 5 all traces of *a*, *b*, *c*, *d*, and *e* should have been made at the same time. Any tilt, curvature, etc. of the shock wave in the aluminum will cause distortion or displacement of these traces, so that the segments *a* should lie on a straight line perpendicular to the direction of motion, the spacings *ab*, *bc*, etc. should also correspond to the physical spacings of the slits in the plate over the charge. Thus, the segments *a*, *b*, and *c* show the quality of the incident plane wave and provide a time zero for each slit. The vertical distance *aa′* multiplied by the known scanning rate of the camera gives the time between the shock wave hitting the shim and the bottom of the groove hitting the shim.

If d is the depth of the groove, U_3 the shock velocity in the aluminum and u_{f_3} the free-surface velocity of the aluminum, this time is obviously $t = d/u_{f_3} - d/U_3$. Now as discussed above, $u_{f_3} = 2u_3$, and this equation may be written

$$1/V_B = t/d = 1/2u_3 - 1/U_3 \qquad (10)$$

From (5), $P_3 = \rho_2 U_3 u_3$, where P_3 is the pressure in the aluminum behind the shock. With (10) and the data of Figure 2 a plot of V_B vs P_3 can be prepared. From the data of slits 1 and 5 several independent values of V_B and hence P_3 can be determined, and hence the pressure of the shock wave in the aluminum and its uniformity over the plate can be measured.

This experimental layout was developed primarily so that very small samples of material could be used. Referring to the lower section of Figure 4 the pellet B is a disc about 0.750 inch in diameter and about 0.250 inch thick. In Figure 5 the displacement *bb′* gives directly the time necessary for the shock wave to traverse this pellet, and hence U_1 of Figure 1b is measured directly. Then as discussed above under *Theory*, the line *OD* of Figure 2 may be drawn and P_1

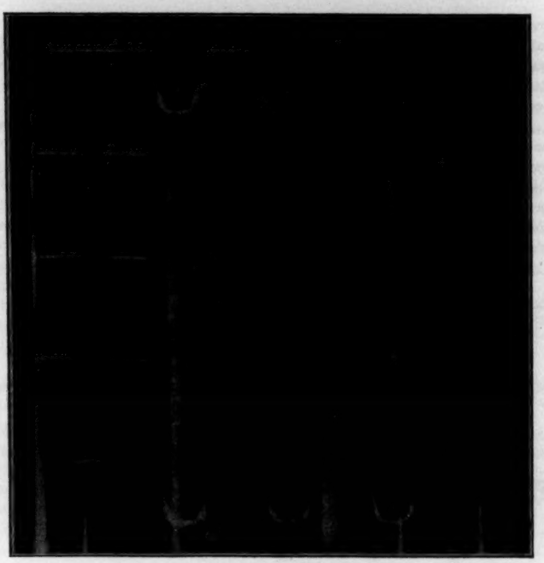

FIG. 5 – Reproduction of camera record

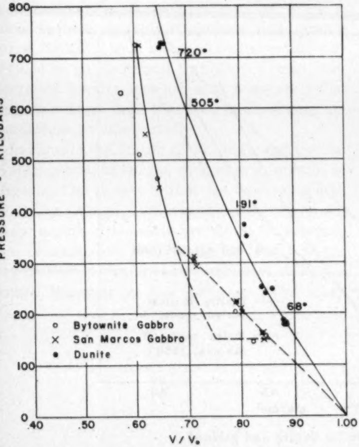

FIG. 6 – Pressure-volume curves of dunite and gabbros

and u_1 of Figure 1 determined. From (4) the compression or specific volume under this pressure is calculated. As shown in Figure 3 there is space for six pellets on each shot.

Figure 5 is a reproduction of the plate obtained on shot 915. The two lower pellets were dunite (from Jackson County, N. C.), the two on the upper right were San Marcos gabbro (from Escondido, Calif.) and the two on the upper left bytownite gabbro (from Duluth, Minn.). The pellet traces are displaced almost the slit distance in this shot. This is a particularly good record in that all pellets gave a good clear trace.

Discussion of results—The gabbros sometimes gave a very irregular, wavy trace. The irregularities correlate roughly with specimen quality; the bytownite gabbro contains crystals 5 to 10 mm in diameter, while for the San Marcos gabbro the crystals are only 1 to 2 mm in diameter. In Figure 6 it is seen that the spread of bytownite gabbro points is much greater than that of San Marcos gabbro points. Further, the bytownite gabbro points that fall off the curve in Figure 6 are all of low density, 2.80–2.85 instead of 3.0 g/cc. The data on the dunite also shows considerable spread, although this rock is homogeneous. Complete petrographic descriptions of these rocks have been published [*Hughes* and *Maurette*, 1957].

Despite the scatter of the dunite points, the Hugoniot curve obtained is typical of that found for most solids. The gabbros, however, have an unusual property; the wave velocity is constant up to 300 kilobars, after which the shock velocity versus particle velocity curve again assumes a typical slope (see Fig. 7; the zero-pressure wave velocity plotted in Fig. 7 is that obtained from *Hughes* and *Maurette* [1957]). Such a curve is evidence of a polymorphic transition [*Minshall*, 1955; *Bancroft*, 1956] where the disturbance, instead of consisting of a single shock wave, manifests itself as two shock waves propagating at different velocities. The first wave propagates into undisturbed material and the state behind it is a point on the transition phase line for which the transition is just beginning to occur. The second shock wave propagates into the latter state and, depending upon the strength of this shock wave, the state behind corresponds to either a complete or incomplete transition. If the pressure carried by the second disturbance is sufficiently high, the transition is complete and the two waves coalesce (or, rather, in the present experiments, never separate). The data for the present gabbro are compatible with a polymorphic transition in the vicinity of 150 kilobars and an associated two wave structure, for pressures behind the second wave which are less than 300 kilobars. Obviously, the impedance-match solutions and consequent pressure-compression data for the gabbros in the 150–300 kilobars depend upon the assumption of a single shock wave and are invalid.

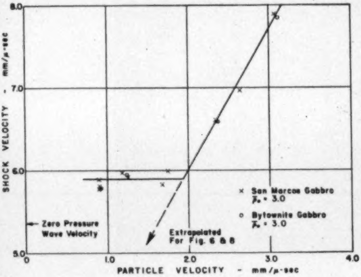

FIG. 7 – Shock propagation velocity vs particle velocity for gabbros

The above argument rests basically on the fact that the data of Figure 7 should be represented by two straight lines rather than a curve.

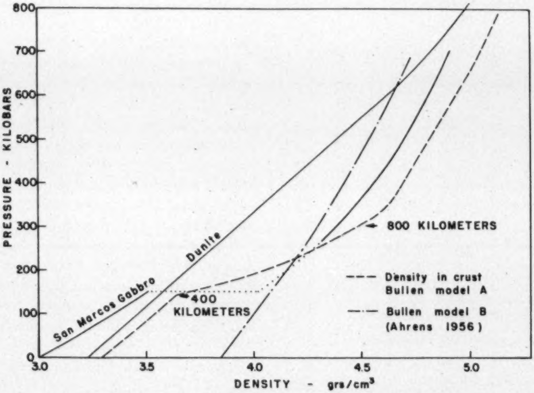

FIG. 8 – Density vs pressure for dunite and gabbros

We now have very good data on 27 metals, two ceramics, Plexiglas, and 17 alkali halides. For all these materials the plots of the relationship shock velocity to particle velocity are very accurately straight lines. Further, the slope of these lines is very closely correlated with the hardness of the material. The ceramics, plastics, and the alkali halides give slopes about the same as Figure 7 beyond 2.0 mm/μsec. The metals show about the same slope as the straight line that could be drawn through the points below 2.0 mm/μsec. Thus, however we interpret the data, it seems evident that the gabbros are quite different materials in the two ranges [*Duff* and *Minshall*, 1957].

If a material has a transition at, say, 100 kilobars, and is subjected to a greater pressure, a wave carrying 100 kilobars will run followed by a wave in the 'new' material carrying the remainder of the pressure. With single-shot methods such as we used here we can only observe the first wave. Hence, for all pressures above 100 kilobars we would only observe a 100 kilobar wave until the pressure rose high enough that the velocity in the 'new' material is faster than the 100 kilobar wave.

The relationship of P to ρ for the gabbros, Figure 8, has been computed on the assumption that these rocks undergo a polymorphic transition in the neighborhood of 150 kilobars. The transition is indicated by a constant pressure line which is joined to the downward-extrapolated high-pressure curve. Actually, such a zero slope line would correspond to an isothermal transition. Energy consideration for the dynamic case, however, would indicate a finite slope which the present data are not sufficient to determine.

In Figure 8 the density of the dunite and the San Marcos gabbro have been plotted as a function of pressure. The density within the crust computed by Bullen [*Ahrens*, 1956] on the basis of two different models of the earth are shown for comparison. It is apparent that the Bullen Model A density-pressure curve is closely represented by the dunite Hugoniot at low pressures. The sharp break in the Bullen Model A curve at 400 kilometers (about 150 kilobars) is also compatible with an assumed gabbro structure at that depth and the associated polymorphic transition. Finally, there is again good agreement between the gabbro Hugoniot and this model at pressures above 300 kilobars.

It is planned to extend the present shock-wave work by using pure minerals corresponding to the important constituents of these rocks. Such materials should, in particular, permit precise Hugoniot measurements and a more complete experimental study of any transitions.

Acknowledgment—This work was done under the auspices of the Atomic Energy Commission.

Discussion of "Sky Temperatures in the Imperial Valley of California"

BY C. F. KELLY, T. E. BOND, AND N. R. ITTNER

[*Trans.*, **38**, 308–313, 1957]

Alice M. Stoll (Aviation Medical Acceleration Laboratory, U. S. Naval Air Development Center, Johnsville, Pa.; received Oct. 10, 1957)—It is gratifying to see that progress is being made along the lines of evaluating the cooling power of the sky with respect to physiological thermal exchange.

This paper recalled to mind a body of data collected by *Sissenwine* (then Head of the Environmental Physics Unit, Research and Development Branch, Military Planning Division, Office of the Quartermaster General) and others [1951] in July and August of 1950 in Death Valley. The proximity (about 250 mi) and obvious similarities in climate of this locality and Imperial Valley are such that there should be, and in fact are, similarities in the observed data, some of which, for ready reference and by way of example, are shown summarized in Table 1. The instruments used are described by *Sissenwine* and others [1951], *Richards* and others [1951], and *Stoll* and others [1952]. The table headings are largely self-explanatory. The sky temperatures shown are for an angle of about 1.1 steradians

[a] This is essentially Table 8 of *Sissenwine* and others [1951]; published with the permission of the Regional Environments Research Branch, Environmental Protection Research Division, Quartermaster Research and Development Center, U. S. Army, Natick, Mass.

[b] Interpolated from observations usually made within ½ hour of the Panradiometer observation.

[c] Assuming that man exposes a spherical surface of 1 m² to radiation, that his emissivity for solar radiation is 0.5, and his emissivity to radiation exchange with his surroundings is 1.0.

[d] Time at start of observation requiring about 20 minutes. Apparent local (sun) time is six (6) minutes later than Pacific Standard Time.

[e] The Sky Temperatures appear inconsistently high with regard to other temperatures preceding and following these observations on the same day.

with the radiometer directed as close to zenith as possible without including direct sunlight. It is seen that the sky temperature in this region, so measured, averaged about 50°F lower than the air temperature, while the soil surface temperature was about 10°F higher than air temperature, and the average radiant temperature, weighting surface and sky equally, was then about 20°F lower than the average air temperature of about 113°F. However, the radiant temperature of the surroundings as measured by the Panradiometer, a non-directional instrument, was only about 7°F lower than air temperature and may be of interest to the authors in comparisons with their values obtained with the Globe thermometer. In any event, the information contained in this report in its entirety should be of value in providing much comparative data particularly since the Eppley pyrheliometer was used in both studies and thus provides a common point of reference for correlating data from several different instruments.

The authors are to be commended for their contribution to this phase of climatology in which data in a form suitable for practical biological applications is at present sparse, scattered and largely uncorrelated with either animal or human thermal exchange.

F. A. Brooks and *John R. Goss* (Department of Agricultural Engineering, University of California, Davis, California; received Nov. 1, 1957)—It seems proper to point out why the authors did not find good agreement between calculated and observed sky temperatures when using the values of *Goss* and *Brooks* [1956] and *Anderson* [1952, p. 92] for the constants in Brunt's empirical nocturnal atmospheric radiation equation.

The data presented in Figure 5 were obtained during the daytime with the Gier and Dunkle *directional* radiometer pointed at the north sky at a 60° angle above the horizon which is nearly the coldest spot in the sky hemisphere. The values for Brunt's constants reported by Goss and Brooks and by Anderson were obtained from data recorded with the Gier and Dunkle total *hemispherical* radiometer during the nocturnal hours in the absence of short-wave radiation. It is presumed that the authors did not correct their data presented in Figure 5 for scattered, incoming short-wave radiation, although this correction would be small since the Gier and Dunkle directional radiometer has a diaphragmed aperture half angle of only eight degrees.

The equivalent sky temperatures observed by the authors (under clear skies) are therefore lower than if based upon the total incoming atmospheric radiation from the upper hemisphere, and hence call for a smaller value for a in Brunt's equation. Furthermore, since the authors used current vapor-pressure readings throughout the day, a greater variation in b would be expected than for vapor pressures measured only when convective turbulence was fully developed.

C. F. Kelly (Department of Agricultural Engineering, University of California, Davis, California), and *T. E. Bond* (Agricultural Research Service, U. S. Department of Agriculture, Davis, California; Authors' closure)—The authors appreciate very much the constructive comments on the paper by both Miss Stoll, and Goss and Brooks. We hope that the net result of the paper and discussions will be to make both meteorologists and engineers more aware of the possibilities in cooling, as well as heating, by exposure to the sky in the proper manner.

Miss Stoll's data for Death Valley are very interesting. The comparison with Imperial Valley is probably not as direct as suggested, because of the greater humidity in the Imperial Valley during the hot summer months, caused by southerly winds bringing in large amounts of moisture from the Gulf of California, and to the irrigation in the valley. The reason for our work in this area is to promote the raising of livestock. The main hindrance to summertime feeding of beef cattle and to dairying has been the drop in rate of gain or of production in the summer. It was early in our studies that Ittner, the livestock specialist of our research team, decided that the high night temperatures did not give the animals an opportunity to cool off as a preparation for living through another hot day. The reason for the high night temperatures is the blanket of relatively moist air over the area. In this respect Imperial Valley differs from a true desert climate. This also, we believe, explains why we obtained differences between daytime air and sky temperatures of 20 to 30°F, while Sissenwine's data indicates an average difference of 50°. It would be interesting to see how these temperatures respond to Brunt's equation, if vapor pressure data were available.

All comments by both Miss Stoll and Goss and Brooks are well taken, and we hope that their discussions will clarify our results adequately.

Discussion of "The Accuracy of Wind-Speed Estimates at Sea"

BY CHARLES F. BROOKS AND ELEANOR S. BROOKS

[*Trans.*, **39**, 52–57, 1958]

G. Verploegh (Koninklijk Nederlands Meteorologisch Instituut, De Bilt, The Nederlands)—Investigations into the various factors which influence Beaufort estimates of the wind force at sea are known to have been made on the basis of data of a variety of vessels with and without sail, moving ships and light-vessels. The authors have augmented this list with another set of original data which may be welcomed especially since it is the first time that routine observations of ocean weather ships were used for that purpose. According to the title of their paper the accuracy of the wind-speed estimates was their main object of investigation.

Now the word 'accuracy' is a rather dangerous one especially when it is used in a qualitative sense without mentioning in what respect and for which purpose the data are to be considered as accurate or not. When the authors state that "nevertheless, anemometer speeds are *obviously* (italics mine) more accurate than estimates from sea disturbance and may be used with some assurance for determining the errors of the latter" not only do they express a certain feeling rather than an established fact, but also they give an unusual and very specific meaning to the words 'accuracy' and 'error,' since by an error they mean a deviation of an estimated value of the wind speed from the speed measured at a height of 20 to 30 m above the sea surface. All factors which may bring forth this deviation are thus considered as sources of the 'error' of a wind-speed estimate at sea. Indeed, from this point of view anemometer speeds are obviously more accurate than estimates; however, from a statistical point of view one is equally free to take the estimated values as fixed and consider the deviations of the measured speeds as 'errors' of the latter.

In general the expressions 'accuracy' and 'error' should be confined to the deviations of a measured quantity with respect to the value which is sought by the measurement.

By this critical comment on the use of the words 'accuracy' and 'error' I have not meant to question the validity of the data presented by the authors. On the contrary, they are indeed of much value as an independent confirmation of earlier findings, some of which still needed such confirmation. To my opinion these data might, however, better be viewed in the light of the following scheme.

Both in synoptic meteorology and oceanography the wind speed to be observed on a routine basis has to be defined for a given level above the sea surface. International agreement has settled upon a level of ten meters; now let v be the wind speed at this level and B its equivalent Beaufort number. The conversion of B into v may be expressed as

$$f(B) = v \qquad (1)$$

In general (1) will not be satisfied by the individual observations. We may distinguish

(1) An error ΔB made by the observer when estimating the wind force. These errors may in the first-place result from individual differences of judgment, giving a standard deviation of the observations with respect to the mean of about 0.4 Beaufort (1.5 knots), a value which is confirmed quite well by the observations made by C. F. Brooks personally and mentioned also in the paper. The error ΔB may also originate from 'external' factors such as, for instance, the effect of strong currents on the appearance of wind waves or variations of the plankton concentration in certain areas [*Seilkopf*, 1956], or at changing winds as the authors were also able to demonstrate. These

errors may occasionally amount to about one Beaufort unit and in exceptional cases, for instance over unexpected, very strong sea currents, even to two Beaufort units.

(2) An error Δv in the anemometer reading. If the anemometer is properly exposed (which is still a rather difficult problem on board of a ship) we may assume that the errors resulting from the disturbance of the air flow by the ship itself and from the pitching and rolling of the ship are comparatively small, that is, the error distribution might have an estimated standard deviation of about one to two knots [see, for instance, *Sanuki* and *Kimura*, 1953]. If the wind speed is measured at a height of about 20 to 30 m above the sea surface the vertical velocity gradient will also contribute to a deviation with respect to the wind speed at ten meters. This gradient is highly dependent on the stability of the air layer involved and especially under stable conditions large deviations amounting to five knots or more may be found. Direct measurements of this gradient in relation with the thermal structure of the air have been made by various investigators; as a classical example of a large velocity gradient I may recall the case of a sailing ship which was driven for hours through a flat sea at six knots' speed with the wind only blowing into the top sails (Ann. Hydr., 1911, p. 576).

(3) An error will also be introduced by the use of a wrong conversion table. As long as the observers are allowed to estimate the wind force in Beaufort numbers the conversion into wind speeds in m/sec or knots will only be the concern of the meteorologist receiving the report and will not interfere with the estimate itself. But when the observers are asked to report the wind speed directly in knots, that is, in units which apparently are too small for a practical estimate, they will naturally tend to round off their estimates to easy numbers as the authors have demonstrated very clearly. If then a wrong conversion table is used systematic errors will be introduced. I think it is important to add this conclusion to the findings of the authors. The use of a wrong conversion table may provide another source of systematic error on board ships that are also equipped with an anemometer. On these ships the observers naturally tend to check their estimates afterwards with the readings of the anemometer 'just to be sure'; after a while the Beaufort estimates will become modified according to the conversion table used. It is therefore not surprising that the authors found a close agreement of the equivalent speeds as computed from the routine observations of the ocean weather stations with the present international scale. If, for instance, the international scale of 1926 were still in use, then, most likely, an agreement with these earlier equivalent speeds would have been found.

From this short review of the magnitude of the errors ΔB and Δv we may conclude that, since the Beaufort estimates relate to some average wind speed of the lower air layers and since, in general, direct measurements of the wind speed on board ship cannot properly be made at a level below 20 m, the accuracies obtained by both methods of determining the wind speed at ten meters are of the same order of magnitude, the standard error being in both cases about two knots.

Thus Beaufort estimates from sea disturbance may be considered about as accurate as wind-speed measurements made at a height of 20 meters or more above the sea surface.

There is another point which needs clarification. The authors have demonstrated a certain dependence of the observed differences between estimates and speed measurements on the thermal structure of the air as represented by the difference of air and sea temperature.

In a discussion on this effect much attention was given to the possibility of the observers being influenced by the somewhat different roughness and steepness of the waves raised by winds in a cold or a warm air mass. The authors concluded that 'warm winds over colder sea tend to be underestimated and vice versa.' Here again we must be very careful to interpret the word 'underestimated' rightly. If is meant underestimated with respect to a wind speed measured at a height of 20 and 30 m I agree, but when considered in its usual meaning, that is, with respect to the actual wind speed at ten meters, I object to this conclusion.

The observed correlation might be caused by two effects, that is, by differences of the vertical wind-speed profile above cold or warm water and by the above mentioned effect on the estimates. The question is which of the two effects is the most important one.

In order to find an answer to this problem I investigated the data of two Netherlands lightvessels on the possible existence of the latter effect [*Verploegh*, 1956]. Now on board these lightvessels the exposure of the anemometers was such (7 m), that a difference of the vertical wind-speed profile in dependence of the thermal air structure would hardly be perceivable when comparing the estimates and the measured wind speeds.

The absence of any correlation between the wind-speed differences on one hand and the air-sea temperature differences on the other led me to the conclusion that, if the observers really were influenced by differences of the wind waves in relatively cold or warm water, the effect on the estimates would still be too small to be detected in routine observations. That is the reason why I think that the correlation found by the authors on the basis of wind data measured at a height of 20 and 30 m refers mainly (if not wholly) to the differences of the vertical wind-speed profile and that we perhaps do better not to describe deviations of this kind as errors of the wind-speed estimates.

VERPLOEGH, G., The equivalent velocities for the Beaufort estimates of the wind force at sea, *Kon. Ned. Met. Inst., Meded. Verhand.*, **66**, 1–38, 1956.

Eleanor S. Brooks (c/o E. L. Stabler, Golf Club Road, Greenwich, Connecticut, Author's closure) —I agree with Verploegh that a comparison of the accuracy of wind-speed estimates and measurements at sea is difficult, because as our paper states, "We have no standard true wind speed such as might be obtained from a fixed anemometer. We are comparing winds at different levels using two methods subject to different types of error." Our opinion that wind speeds obtained from anemometers are more dependable than those estimated from sea disturbance is, I believe, generally held. Otherwise, why should anemometers be installed on weather ships and large merchant ships?

The sea surface used as a wind-speed indicator might be likened to an anemometer with a large lag effect. This is apparently a frequent source of difficulty in making estimates. Taking our instances in which estimated Beaufort was below the measured value, we found increasing winds in slightly more than half the cases. Conversely, when estimated Beaufort exceeded measured Beaufort there were decreasing winds 70 pct of the time.

Verploegh suggests that estimates of wind speed are likely to follow too closely the anemometer measurements when both are made on the same ship. The systematic differences cited above show some independence between the two sets of observations.

When the data were obtained for our study, the observers were asked to make their estimates of wind speed from sea disturbance directly in terms of the Beaufort scale. As Verploegh says to have attempted estimates in knots would have been quite impracticable. The paragraph in our paper (p. 54) referring to the rounding off of figures recorded in knots, applied to anemometer data, not to estimates, and apparently was misinterpreted by Verploegh. I regret any ambiguity.

The effect of sea-air temperature differences on the vertical temperature distribution and wind-speed profile, and consequently on the height and steepness of waves has been described and measured by H. U. Roll, R. G. Fleagle, and others whose work is cited in our paper. The observer will necessarily be influenced by the character of the waves, as they are the basis of his estimate of wind speed. Hence this seems to me all part of one effect and hardly to be separated into two. I would agree with Verploegh that the effect is more marked when the anemometer is high above the sea surface. In his series of observations (1956) the anemometer was below the standard height for Beaufort conversion, in ours, above.

Discussion of "Correlation of Rainfall Intensity and Topography in Northern California"

BY RAY K. LINSLEY

[*Trans.*, **39**, 15–18, 1958]

W. T. Wilson and *D. M. Hershfield* (U. S. Weather Bureau, Washington, D. C.)—For several years investigators have faced the problem of deriving rainfall intensity-frequency values for regions where observations of short-duration rainfall are sparse or lacking. Our experience with synoptic, climatic, and topographic parameters has been that while parameters for slope, barrier

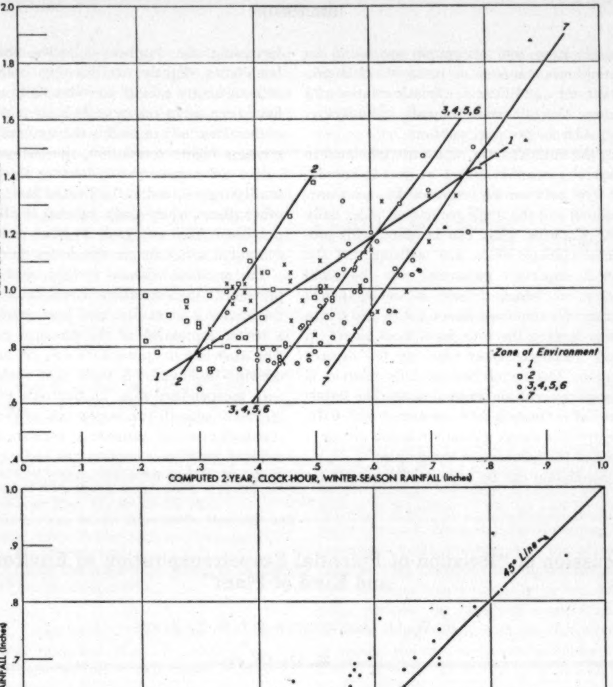

FIG. 3 – Relation between two-year, clock-hour, winter-season rainfall and index daily rainfall in four zones of environment in northern California

height, elevation, and orientation are useful for estimating mean annual or mean seasonal precipitation, they add little to climatic relations for estimating short-duration rainfall intensity-frequency, such as two-year one-hour.

Using the author's data, which are tabulated in the third reference of his paper, we found a correlation of 0.68 between winter-season two-year one-hour rainfall and the single parameter 'index daily rainfall.' Knowing what can be done with orographic or climatic zones, and realizing that the next most important parameter was the zonal parameter, we added it next in our graphical correlation. We combined Zones 3, 4, 5, and 6 into one zone, leaving the four zonal lines shown in Figure 3, which consumes relatively few degrees of freedom. The correlation for this relation is 0.83, compared with the author's 0.88. The standard error of estimate is 0.08, compared with 0.07. Apparently this simple climatic relation accounts for much of the influence of topography.

The correlation can be improved, of course, by increasing the number of zones, shifting their boundaries slightly, or drawing isolines of the ratio of hourly rainfall to index daily rainfall. We have been using two-year 24-hour rainfall instead of the index daily rainfall in the latter ratio. Besides giving a higher correlation, the two-year 24-hour values are necessary for defining the rainfall intensity regime; and in the United States and many other places where daily rainfall is observed and published, the two-year 24-hour value can be computed as easily as the index rainfall.

The question arises as to how much of the improvement in correlation would be a product of the analyst's ingenuity, and how much would be a better expression of the physical relationship. Any correlation up to 1.00 can be achieved by drawing isopluvials. A valid test could be made with independent data. In our own work we deliberately smooth the isopluvials so that the final standard error of estimate is consistent with the residual error of sampling, as determined from study of dense network data.

Discussion of "Relation of Potential Evapotranspiration to Environment and Kind of Plant"

BY W. O. DRINKWATER AND B. E. JANES

[*Trans.*, **38,** 524–528, 1957]

M. A. Kohler (U. S. Weather Bureau, Washington, D. C., received Oct. 23, 1957)—The authors cite the need for re-examination of methods because of inconsistencies and indicate that they have followed *Mather's* [1951] method of installing and operating modified evapotranspirometers. While it is stated that two plants were grown in each of the corn and celery tanks, no mention is made of tank size or how the number of plants was selected. It is believed that the results would have been quite different had one or three plants been grown in each tank. *Suomi* [1953] and *King* and others [1956] have shown that the effective area of an evapotranspirometer cannot be assumed to equal the actual area, even when great care has been exercised with respect to plant density.

It was of interest to note that the authors chose to derive solar radiation from black-minus-white atmometer values in preference to sunshine duration. Since the correlation analysis (Table 1) indicates that sunshine duration *per se* is the better index, radiation data derived therefrom [*Hamon* and others, 1954] would undoubtedly be superior.

The authors stress the advantage of 'natural periods' over arbitrary seven-day periods in correlation analysis, and cite an early paper by *Penman* and *Schofield* [1941] in support of this contention. Since the tanks were watered daily in this case, however, it is difficult to see the need for breaking the record into 'between-rain' groups. It is inconceivable that the correlation (measured versus computed PE) should increase from 0.40 to 0.97 by changing from seven-day to between-rain data, unless the total period PE was improperly used as the dependent variable instead of the mean daily PE. By this technique, one can demonstrate a high degree of correlation between two factors which bear no relation whatever on a daily basis. The spurious correlation results from the introduction of a third variable, the length of the period.

It is regretted that the basic data of Table 2 could not have been published in more detail.

Seasonal values (inches per day) cannot readily be compared when the period constituting the season changes from year to year. In the form shown, the data in this table appear inconsistent in numerous respects. For example, the relative black-atmometer evaporation in 1953 and 1954 is counter to what might be expected from any other type of data listed. All measured PE values in 1953 and 1954 exceed the actual Class A pan evaporation, which means they greatly exceed free-water (shallow lake) evaporation. Such values appear excessive in the light of energy considerations as applied to extensive, uniform areas.

SUOMI, V. E., *Heat budget over a corn field*, Ph. D. thesis, Univ. of Chicago, 36 pp., 1953.

Edgar E. Foster (2232 Prune Ridge Ave., Santa Clara, Calif.; received Nov. 1, 1957)—The investigation reported on in this paper apparently indicates that there may exist a fundamental defect in the so-called energy-budget method of computing evapotranspiration and that the same defect exists in any method of computing evaporation from climatic elements. When the methods referred to are applied over a period of time sufficiently long so that averages are reasonably stable, the defect may not be important, but for short periods of time it does seem important. However, the change in relationship between evapotranspiration and heat, as indicated by the computed and observed values, from rain to rain, indicates that there exists another factor.

The paper does not make clear the effect of changes in soil moisture from time to time. This could make a difference. However, it seems that the experimentation would be conducted so that this would not be an important factor. Likewise, if it were, it seems that the agreement between computed and observed evapotranspiration would not coincide so regularly with the days of rainfall.

The one meteorological element not included in the energy budget (or analogous computation based on climatic elements) that would vary with the occurrence of rainfall is the humidity. The relationship between humidity and evaporation was pointed out many years ago by Dalton. This relationship has been retained in many common formulas proposed for computing evaporation, such as, for example, Rohwer's

$$e = 0.771\,(1.465 - 0.0186B)\,(0.44 + 0.118W)(e_s - e_d),$$

Where e = evaporation
B = barometric pressure
W = wind velocity
e_s = the vapor pressure of saturated air at the temperature of the water surface
e_d = mean vapor pressure of the air above the water surface

The energy-budget methods or methods based on climatic data do not contain a factor to account for the effect of humidity, that is to say, the difference in humidity of the air and its saturation vapor pressure. Since it is the difference between saturation vapor pressure and the actual vapor pressure that controls the evaporation and since this difference would normally be less during the rainy periods, the observed evaporation should be more in agreement with the computed, which is usually the case as shown in Figure 2. Therefore, it appears that this factor of humidity should be included in the method of computed evapotranspiration or evaporation.

Did the experiments include observations on humidity so that this viewpoint could be examined?

W. O. Drinkwater and *B. E. Janes* (Storrs Agricultural Experiment Station, University of Connecticut, Storrs, Connecticut; Authors' closure)—Kohler and others have indicated the effective area of evapotranspirometers is difficult to determine. For the grass tanks the actual area, 380 sq inches, was assumed to be the correct effective area. The height of the grass was maintained at about 1½ to 2 inches by clipping once a week. The rim of the tank, which was approximately ¼ inch thick, was one inch above the ground surface. The soil surface in the tanks was approximately the same height as surrounding area. The grass covered the rim of the tank so that it was not visible. The effective area of the tank for celery and corn is not necessarily that of the tank. The plants do not cover the entire area and portions

TABLE 3 – *Corrected correlations of measured PE (Unit I) with several climatic elements with data grouped into between-rain periods and seven-day periods*

of them extend beyond the rim of the tank. An attempt was made to have the same plant density in the tanks as in the surrounding areas, 12 inches apart for corn and six inches for celery. (Line 12, page 524 of paper should read: Two plants were grown in each corn tank and three plants in each celery tank.) This spacing was satisfactory for length of row. The rows in the field were spaced three feet apart. Each celery plant then occupied an area 6 × 36 inches or 216 sq inches. The area for each plant in the tanks was only 126 sq inches. The effective area for rainfall accumulation in the tanks was 380 sq inches but for absorption of radiation changed as the plants grew. When the plants were small the area of the tank was the effective area, however, as the plants grew the area of absorption of radiation increased. For the present study the area of the tanks was considered to be the effective area for both celery and corn.

The authors chose to use the difference in loss of water from black and white atmometers as a measure of solar radiation for two reasons. Duration of sunshine is based on an arbitrary standard of intensity above which point the Sun is shining and below which it is not shining. However, the atmometers are influenced by intensity of radiation and thus are more representative than duration. Atmometers are simple and inexpensive to operate making it possible for measurements to be made in a greater number of situations than duration which requires expensive recording equipment.

As suggested by Kohler, the correlation of PE and climatic elements grouped on a between-rain basis (Table 1) were incorrectly calculated. The correct values based on daily average values for the periods rather than totals for the periods are given in Table 3. The corrected values of r for the correlation between computed PE and measured PE based on between-rain periods were $r = 0.34$, -0.48 and 0.66, for 1953, 1954, and 1955 respectively. The 1955 value $r = 0.66$ was the only correlation which was significant. Changing the values used to plot the curves for between-rain periods (Fig. 2) from totals to averages also indicated a change from good to poor correlation. The corrected values indicate that relating PE measured from evapotranspirometers to climatic elements, there is little to be gained by grouping into between-rain periods. However, because of the value of between-rain periods in interpreting irrigation response, it would be desirable to use them in studying evapotranspiration phenomena in relation to irrigation.

Discussion of "Flood Frequency by Regional Synthesis"

BY R. ROBINSON ROWE, GORDON L. LONG, AND THOMAS C. ROYCE

[*Trans.*, **38**, 879–884, 1957]

Manuel A. Benson (U. S. Geological Survey, Washington 25, D. C., received Feb. 12, 1956)—This paper represents an unrestricted, though unmentioned, acceptance of the station-year method for annual-flood data. Experience shows that annual-flood peaks at gaging stations within even wide regions are not independent events, particularly for the higher peaks; hence the station-year method is apt to give misleading results. Note that the resultant regional curves shown in the authors' Figures 4 and 5 are to the right of the general positions of the individual frequency curves and do not represent the central tendency. This is due to (1) use of the station-year method, and (2) use of a straight line, which, at least in northwestern California (Fig. 4), disregards the curvilinear tendency of the individual records. The resultant curves may provide discharges which are too low for conservative design.

The combining of 12 station records, 15 to 45 years in length, to give 314 years of record, and the augmenting of this by means of a plotting-position computation which leads to a frequency curve defined up to 628 years, appears questionable to this writer. After all, only 45 years of flood experience are represented by the original data. Even were all the data spatially independent, there still remains a grave question as to whether the experience within a 45-year period can duplicate the pattern and range of experience within 628 years.

In the past the writer [*Benson*, 1952] has performed a statistical sampling test on a theoretical 1000-year flood record, with results comparable to those of the authors. The application of the unscrambling method to a composite curve as a test of homogeneity seems overly laborious and rather vague. The writer's study referred to above shows that chance sampling led to a spread (95 pct of the time) within roughly 25 pct of the mean value at any range. The authors' sample curves, Figures 2 and 3, appear to confirm this, and the 25 pct spread would appear to be a satisfactory simple criterion for homogeneity.

In the Sierra Nevada study the authors used the California plotting position, $T = Y/M$; in the other, they used the Hazen plotting position, $F = Y/(M-\frac{1}{2})$. The latter was done in order to offset the 'upward bias' introduced by the December 1955 flood. The selection of plotting positions appears to be too subjective and this procedure, at least, should be standardized.

The writer agrees with the concept of defining regionally applicable composite curves. However, the use of the station-year method should be restricted to events known to be independent. In general, for annual peaks, combining so as to produce a median curve better defining the general relationship during the period of record is more often warranted than combining end-to-end so as to produce an artificially long period of time.

Incidentally, the position of the northwestern California curve on Figure 6 does not agree with that on Figure 4.

REFERENCE

BENSON, MANUEL A., Characteristics of frequency curves based on a theoretical 1000-year record, U. S. Geological Survey, open file, 21 pp., August 1952.

Ray K. Linsley (Stanford University, Stanford, Calif., received Feb. 19, 1958)—A number of recent papers have treated the subject of flood frequency and especially the synthesis of regional frequency curves. The writer is well aware of the limitation of frequency analysis but some aspects of this most recent paper bear closer scrutiny. The authors present a concise explanation of the uncertainties of current plotting position formulas especially as they relate to the higher floods of a series. Their own table (p. 880) shows that the odds are roughly two to one that the highest flood in a series has a true return period longer than that given by conventional formulas. They then take actual frequency plots and draw so-called 'bilinear graphs' in an attempt to fit curves as closely as possible to the plotting positions which they have criticized. They justify this on the basis that there are two 'populations' in the flood series being sampled. If there are two populations these should be explicitly defined and the data separated on a logical basis into the two series before frequency analysis.

In the California mountain regions it is conceivable that two populations can be defined and studied separately. One would result from rain floods such as that of December 1955. The other population would consist of snow-melt floods which enter the annual flood series only in years when there are no significant rain floods. It should be relatively simple to recognize these two types in the record and then prepare the two distinct series required. It is quite possible that either or both of these series will also plot with a 'dog leg' and that in the majority of the cases the dog leg will break upwards since, as already noted, the odds are in favor of having floods in the series with true return periods greater than that by conventional plotting formulas. If so, it is hard to accept the argument that the frequency curve must be drawn by eye through the plotted points. Is it not better to make the most of all the data by fitting a statistical function than to allow the few high points, which are most likely to be in error, to determine the location of the curve?

As a test of homogeneity the authors develop a synthetic scatter pattern of frequency curves and propose that if the scatter among a group of curves plotted from actual flood data on several basins is "not greater than the chance distribution, the stations may be treated as homogeneous."

Is this a valid test of homogeneity? Is it fair to say that because two frequency curves do not diverge by more than the scatter in a chance sample that the basins are in fact homogeneous? Is it not possible that some of the differences between the several curves on Figures 4 and 5 are real differences? It seems quite reasonable to the writer to suppose that they are. There is a vast range in basin size and shape, a considerable difference in topography and mean annual rainfall, and a variation in mean elevation. This latter factor has a significant effect on the flood characteristics of a basin by controlling the portion of the total basin area contributing runoff from rainfall during a storm. In addition, many of the streams are regulated by reservoirs which may substantially affect the lesser floods. The effect of area alone can be very significant. The smaller basins will produce their maxima from relatively short, high-intensity rains, while the larger basins require a large total volume of rainfall to produce major floods. A small basin can be expected to receive at some time a higher average rainfall than a large basin will ever get, all controlling factors being equal. Since the relation between rainfall and runoff is curvilinear, greater depths of runoff should be anticipated during extreme floods on smaller basins than on the larger basins. Because, however, the paths of storms are more or less randomly distributed a small basin does not get the maximum rainfall in all storms and thus will produce many annual floods of no greater relative magnitude than those on the large basin. One might expect a steeper slope to the frequency curve of the small basin. The use of flood ratios instead of actual peaks will not mask this effect nor the effect of other factors which determine the flood producing characteristics of rivers. A test of homogeneity must rest on more than comparison with a synthetic chance sample. It should attempt, at least, to consider the physical features of the basins concerned.

The summation of a number of short records into a long record is the station-year approach which was suggested for rainfall data by the *Miami Conservancy District* [1936] and has since been substantially disqualified [*Hafstad*, 1942]. A significant problem here is the question of independence of the records which are combined. The data presented by the authors include a group of basins in close proximity and all basins in the group are affected simultaneously by a large general storm. Indeed, they even include more than one station on the same river. The error here is obvious if one considers the situation of combining only three stations on the same stream (for example, Kings River, Fig. 5). If there are 20 yr of record at each station and the highest peak at all stations occurred during the same flood, this flood is automatically assigned a return period of 60 yr at one station, 40 yr at the second, and 20 yr at the third (using $F = Y/M$).

In their conclusion the authors state "... in the extrapolation of frequency graphs for peak discharges large errors can be reduced by combination of non-dimensional flood ratios of several streams into one synthetic record." The proof for this is supposed to lie in Figures 4 and 5 but these figures show only a group of individual basin frequency curves with considerable scatter and a single synthetic curve. The writer can find no proof presented that the synthetic curve is any more reliable than the individual curves. It might be suggested that we should not attempt to extrapolate frequency curves substantially beyond the record length. If extrapolation of short records is necessary, there are available reasonably sound hydrologic procedures as outlined by *Kresge* and *Nordenson* [1955] and *Paulhus* and *Miller* [1957].

David M. Hershfield (U. S. Weather Bureau, Washington, D. C., received Mar. 14, 1958)—The authors have tackled the important hydrologic problem of flood frequency analysis with the purpose of improving the flood frequency estimates of individual streams by making use of all the data in a 'climatically homogeneous' region rather than short single station records. Although the problem of short-record estimates occurs frequently, it is a mockery to tell the design engineer that his sample is too small for reliable estimates. The engineer, as the authors have done, might resort to some form of regional analysis in an attempt to improve the quality of the estimates. However, if this problem is not recognized as a

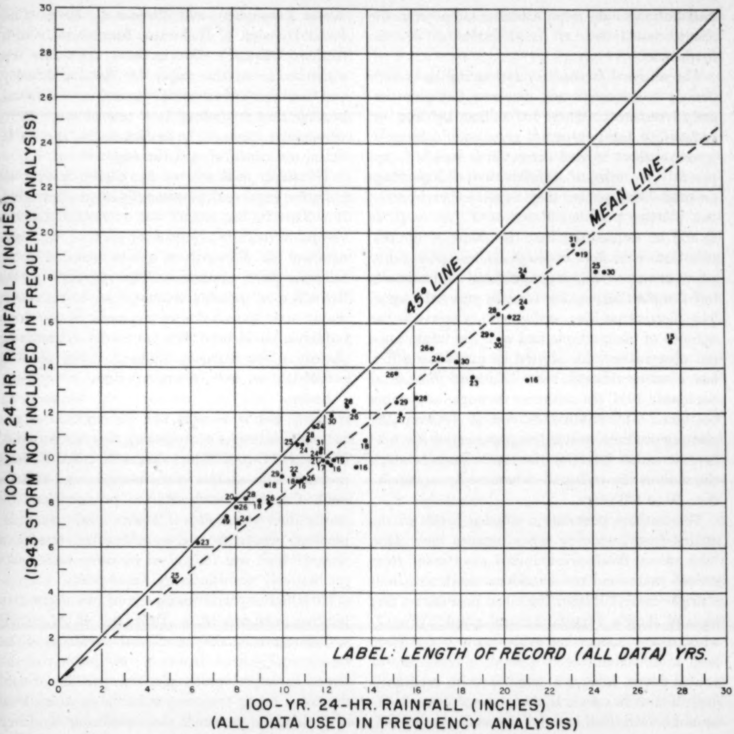

FIG. 7 – Comparison of 100-year 24-hour rainfalls for stations in the Los Angeles, Calif. area

statistical one, the predictive value of the results are vulnerable to serious criticism.

Because of the statistical nature of the problem, the important condition of independence must be met; that is, each extreme is independent of the other extremes. This condition is closely approximated for distributions at individual stations where each of the extremes (maximum annual values) represents the extreme of a large number of independent observations of the variate. When all the extremes or statistics based on these extremes are combined to form one long-record synthetic distribution, the condition of independence is violated if some of the observations are the result of the same event.

The combining of large rainfalls associated with the storm of January 1943 in Southern California is an example of improper grouping of observations from a number of stations in a 'climatically homogeneous' region. Of the records for the 50 stations analyzed in the Los Angeles, Calif., area (approximately 5000 sq mi), 33 had maximum annual 24-hour values associated with this one storm. The maximum annual values for the other 17 stations were associated with other storms. Figure 7 illustrates the effect that this one event has on the frequency distribution. The 100-year values were computed analytically by the *Gumbel* [1941] procedure using all the data and then omitting the 1943 rainfall. Combining all the data into one distribution would mean a biased sample and the result would be an underestimate of the frequencies.

The authors' method for estimating the return periods is subjective and, in some ways, not exactly consistent. They fit a line by eye on probability paper (type not given) and arbitrarily ignore outliers or give them "little weight." Apparently, in order to straighten out the plottings on probability paper, they vacillate between the two plotting positions Y/m and $Y/(m - \frac{1}{2})$. It should be emphasized that the shape of the distribution or the slope of distribution on probability paper changes with, say, additional observations, but the plotting-position formula stays the same. The plotting position $m/(n + 1)$ where n is the number of observations and m is the rank when the observations are plotted in ascending order, has a more rational basis [*National Bureau of Standards*, 1954] than either of the authors' plotting positions. The relative differences between the plotting positions used in this paper and $m/(n + 1)$ become rather large for the return periods which the authors are trying to determine by extrapolation, 30 to 100 years.

The authors postulate a dog-leg break in the annual-flood frequency series because they claim "the annual floods are a mixed assortment from several causes and not a random assortment from a single cause." Rather than just postulate a dog leg and show a "typical bilineal graph" (Fig. 7) without any supporting evidence, it would have been more convincing to present a few series of annual floods, selected at random, with each flood identified as to cause. If the cause of these floods cannot be identified exactly, or even dichotomized, there is obviously no basis for attempting to separate the floods in a frequency analysis. In the statistical analysis of extreme events, all that is needed are the magnitudes of the events (annual floods) which have been obtained by a systematic sampling procedure. The cause of the events does not enter into the frequency analysis. If, however, the cause is known, the annual floods can be symbolically identified on the probability paper.

R. Robinson Rowe (California Division of Highways), *Gordon L. Long* (California Department of Water Resources), and *Thomas C. Royce* (California Division of Highways, Sacramento, Calif.; Authors' closure)—The authors appreciate the attention given this paper by Benson, Linsley, and Hershfield. Much of the discussion was critical, proving that hydrology is a science with many viewpoints; those of the hydrographer, the statistician, the educator, and the engineer.

The paper was written by engineers with an objective expressed purposefully in the introduction. Since its importance was overlooked and the viewpoint requires rejection of most of the arguments of the discussors, it will be repeated in the following brief statement. The objective is the derivation of reliable estimates of 10-yr, 30-yr, 50-yr, and 100-yr momentary-peak floods from published basic flood data for use in determining clearances for highway bridges. Policy inhibits overdesign as well as underdesign.

Benson calls the procedure the 'station-year method,' but it is more like the 'method of obtaining relation for frequency for all streams' [*Fuller*, 1914, p. 580] and should be called Fuller's method. The station-year method was Fuller's method applied much later to precipitation. He warns that treatment of higher peaks as independent events may give misleading results, a hazard which was recognized by using such peaks qualitatively to ordinate the lesser peaks.

He criticizes discretionary use of two alternative plotting positions ($F = Y/M$ and $Y/(M - \frac{1}{2})$) and disregarding the 'curvilinear tendency' of the former on Figure 4. It was not the purpose of the paper to argue which plotting position should develop a linear frequency relation on which kind of probability paper. If the curvilinear tendency is real, the paper or plotting formula is wrong, but the procedure is correct for the objective. Probably the curvilinear tendency is an illusion caused by the infrequency of the 1955 floods.

Benson's unpublished corroboration of random statistical sampling should be noted. If all hydrologists would take the time and trouble to run such a sample just once, they would appreciate the sobering fact that a single historical frequency series is a poor measure of future events. Similarly for the test of homogeneity; once done, the picture of 25 pct spread will suffice for future tests, as he says.

His preference for combining frequency charts laterally into a median curve instead of longitudinally into an artificially long period is difficult to understand. If some events are dependent, both methods overweight them. Median (or mean) curves would not properly weight long records more than short ones.

He correctly points to an error in plotting Figure 6. As this was intended to compare two slopes qualitatively, it is not being revised.

Linsley criticizes the bilinear graphs and claims that it should be relatively simple to separate the two populations so combined. This is not true. Snow-melt floods can be identified; in fact they have been excluded from Figure 5, but dog legs remain. The other set (Fig. 4) is not sensitive to melting snow. To eliminate the remaining dog legs, it would be necessary to (1) define the dominant storm, (2) identify and exclude peaks from recessive storms, (3) replace the excluded peaks with lesser peaks from storms of the dominant type. Even if possible, these substitutions would require a great deal of research, particularly in early records for which only one peak was published for each year.

His objection to the bilinear graph is that it prohibits an analytical calculation of the frequency curve. The paper described a visual fitting of the curve, ignoring the undefined lower limb. Linsley protests that this gives too much weight to high points plotted with unavoidable large errors, but step (8) on page 882 said explicitly, "determine visually a best-fit line for the well-defined part of the graph, giving little if any weight to wild points at the infrequent end." The danger of indiscriminate statistical analysis is the lack of discretion in the method of least squares. Visual methods are preferable and sufficiently accurate, considering the large error inherent in each item of the basic data.

Linsley's questions on homogeneity derive from lack of a definition. Statistically it might be defined as coincidence of non-dimensional frequency curves. By that definition, Elm Creek in Alabama, and Oak Creek in California might happen to be homogeneous, although dissimilar in all other respects. However, even if there is a hydrologic law of nature that all such curves are straight lines on a certain probability paper, definition of the curves from available data is only approximate. Our paper described a test for homogeneity which is really a negative test for heterogeneity. If not excluded by the test, "the stations may be treated as homogeneous," even though homogeneity is only approximate, at best.

He is correct in supposing that some of the differences in the station plots of Figures 4 and 5 are due to climate and terrain rather than chance. But if differences of the two kinds are inseparable, charging all to chance may give more reliable results than charging all to nature. For example, note the station curve on Figure 4 for Scott River (No. 7). Extrapolation of an ordinary frequency curve to 100 yr would give $6Q_5$, instead of $2.4Q_5$ by regional synthesis. Fact, if it could be known, is probably between these two, but the authors contend that regional synthesis gives the more reliable estimate for bridge design.

Most of his suggestions for qualitative tests of homogeneity were considered in the preliminary definition of the region. In particular, the records are practically unregulated, but it is interesting to note that artificial regulation can produce frequency curves with two dog legs, so that some angularity of other curves may be due to natural regulation.

Linsley's statement that the station-year approach has been substantially disqualified is not supported by his reference. It would be more appropriate to say that Hafstad qualified the method by proposing a measure of accuracy based on statistical dependence. Her conclusions were challenged by several discussers. The method is still widely used.

He also questions independence of records on adjoining basins during a large general storm, particularly two or more records on the same stream. Absolute independence is neither claimed nor necessary, but dependence is far from absolute, too. Without some considerable degree of independence it would not be necessary to maintain so many gaging stations. As a measure of independence of stations in the same basin, note in Table 2 the six stations in the Klamath Basin (including Salmon, Trinity, and Scott Rivers). The 1956 flood is rated variously from 100-yr to more than 1000, while adjacent basins recorded only a 17-yr flood on the north and a 37-yr flood on the south.

Linsley decries lack of proof that the synthetic curve is any more reliable than the individual curves. In predictive hydrology there is no proof and none is offered. He suggests that two alternative procedures are "reasonably sound" without describing them as proved. The inconsistency is obvious. The alternatives are not sound for either region synthesized, since precipitation records are fewer in number and shorter in record than stream-gaging stations.

Hershfield concurs in the objective of the paper, but with misgivings over independence of observations of the same event at two stations. This has been answered, but can be restated by the paradox, 'sameness is relative.' He also concurs in disregard of cause of dog leg, but with some curiosity as to that cause. A digression might be interesting but not in point.

His analysis of 24-hr precipitation at 50 stations near Los Angeles to show the effect of bias is incomplete. Suppose he synthesized the data successively with and without the 1943 record. Wouldn't these two curves also diverge by about 20 pct? How does the alleged bias affect flood peaks on streams sensitive to shorter or longer storms?

Like Benson, he criticizes use of two formulas for plotting positions, charging erroneously "they vacillate." He suggests a third formula as more rational. It was not the purpose of the paper to revive this perennial argument, but to illustrate applicability of the method to any rectified procedure.

Summarizing, the discussion has called attention to error rather than mistake. Error of fairly large magnitude was admitted as a premise for systematic reduction. Criticism of use of dependent data was fallacious because (1) dependence is not absolute, and (2) error of exclusion might be greater than error of inclusion. Alternative procedures are less reliable for the objective in bridge design.

Notes and Personalia

Notes

New Earth Sciences Program of the National Science Foundation—The National Science Foundation has announced the establishment of a Program for Atmospheric Sciences in the Division of Mathematical, Physical, and Engineering Sciences, with Earl G. Droessler as Program Director. Proposals for work in this field were formerly handled in the Program of Earth Sciences, of which William E. Benson is the Director. The new Program was established by special congressional action as a result of recommendations of the President's Committee on Weather Control and the Committee on Meteorology of the National Academy of

Sciences—National Research Council established especially to study this program.

Space Science Board of the National Academy of Sciences—A 16-man Space Science Board to survey in concert the scientific problems, opportunities, and implications of man's advance into space has been appointed by Detlev W. Bronk, President of the National Academy of Sciences—National Research Council. Lloyd V. Berkner, President of Associated Universities, Inc., and Vice President of the American Geophysical Union, has been named as Chairman. Others on the Board include: Harrison S. Brown, A. H. Shapley, John A. Simpson, Harold C. Urey, James A. Van Allen, Harry Wexler, and George P. Woollard. Hugh Odishaw has been named Executive Director. Eleven subcommittees have been established to carry on various phases of the work.

Books in the Earth Sciences Needed at the University of Chile—A new School of Earth Sciences is being established at the University of Chile in Santiago and an appeal has been made for books, journals, and other publications bearing on any aspect of this broad field. Prospective contributors should write to Dr. Pierre St. Amand, U.S.O.M. Chile, United States Embassy, Santiago, Chile, to make arrangements to have them shipped at no cost to the donor.

Catalogue of Active Volcanoes of the World—The International Association of Volcanology, IUGG, (Francesco Signore, Secretary, Via Tasso 199, Naples, Italy) announces the availability of Part VI of the Catalogue, Central America, compiled by F. Mooser, H. Meyer-Abich, and A. R. McBirney, at a price of $5.00. Parts I–V relating to (I) Indonesia, (II) Philippine Islands and Cochin China, (III) Hawaiian Islands, (IV) Africa, and (V) Melanesia, are also available. Send orders to the Secretary of the Association.

New Civilian Space Agency—A new law has been passed by the Congress establishing an official space agency combining this with the National Advisory Committee on Aeronautics, which has long been in existence. T. Keith Glennan, President of Case Institute of Technology, has been designated its Chairman.

Plans for Continuation of Igy—At a recent meeting of the International Committee for IGY (CSAGI), with participants from about 60 nations in attendance in Moscow, agreement was reached to continue the work of the IGY through 1959. This still requires the concurrence through financial appropriation of the governments of the various countries.

Availability of Bulletin of the International Association of Scientific Hydrology—This *Bulletin*, published four times a year by the International Association of Hydrology, IUGG, is now in its third year. The subscription rate is $3.00 for the four numbers. While this is published by the Secretariat of the International Association (L. J. Tison, Secretary, 61 Rue des Ronces, Gentbrugge, Belgium), subscriptions may be placed in the United States with Ralph N. Wilson, Secretary of the Section of Hydrology, AGU, at 3322 Stanford Street, University Hills, Hyattsville, Maryland. The *Bulletin* is a ready means for hydrologists the world over to keep up with current work in hydrology in the various parts of the world and includes reviews and news notes.

Availability of Bulletin Géodésique—*Bulletin Géodésique* of the International Association of Geodesy, IUGG, is now published by Pergamon Press and is available on subscription at the rate of $12.60 per volume. Individual subscribers certifying that the journal is for their personal use may subscribe at the rate of $5.60 per year. Send subscriptions to the Pergamon Press, 122 East 55th Street, New York 22, New York, or 4-5 Fitzroy Square, London W.1, England.

First Municipal Water-Desalting Plant to be Built—The first desalting plant for a United States city is to be built at Coalinga, California, this being a plant of 28,000 gallons per day and using an electric membrane. It will be built under contract with Ionics, Incorporated, of Cambridge, Massachusetts. It will increase the city's supply by 50 per cent of the separately distributed drinking and cooking water. It will be used to remove excess minerals from the city's plentiful but brackish well water.

Expanded Agricultural Weather Services for the Mississippi Delta Region—Arrangements are being completed to carry out a pilot agricultural weather-service project designed to provide farmers in the cotton belt of the Mississippi with more frequent and more detailed weather forecasts to meet problems during the growing season involving amounts and times of precipitation, the likelihood of heavy dew, the severity and duration of rain and wind storms, and the range of daily temperatures. The project will involve the establishment of additional cooperative observers, the assignment of additional forecasters to the Weather Bureau office at Jackson, Mississippi, the establishment of a special weather information teletype circuit, and the assignment of a professional meteorologist familiar with agricultural weather problems to work with the Delta Branch Experiment Station at Stoneville, Mississippi.

Conference on Physics and Medicine of the Atmosphere and Space to be Held November 10–12 in San Antonio, Texas—The International Conference on Physics and Medicine of the Atmosphere and Space will be held in San Antonio, Texas, November 10–12, 1958. It will be sponsored by the U. S. Air Force School of Aviation Medicine. Among those participating will be Joseph Kaplan, Chairman of the U. S. National Committee for IGY; Gerard P. Kuiper, Astronomer at the University of Chicago; James A. Van Allen of the University of Iowa, and Fred L. Whipple, Director of the Smithsonian Astrophysical Observatory. Interested persons should write to Southwest Research Center, 331 Gunter Building, San Antonio, Texas.

Establishment of Seismic Reference Service—T. A. Manhart, President of Century Geophysical Corporation, has announced that that company has joined with the Schlumberger Well Surveying Corporation to establish the Seismic Reference Service, which will provide the oil industry throughout the United States with a geophysical velocity logging service. Although Century Geophysical Corporation will continue its headquarters in Tulsa, the American headquarters of the new service are located in Houston.

Improved Hurricane Warning Service for East Coast and Gulf of Mexico Areas—The Weather Bureau has announced that the hurricane warning service of the Bureau has been strengthened considerably as a result of expanded observation networks, additional aircraft reconnaissance, better telecommunications, and other facilities. Much detailed knowledge on the behavior of hurricanes has been gained since the establishment of the Hurricane Research Project at West Palm Beach in 1955. During the voyages of the Coast Guard Cutter *Sebago* in the Gulf of Mexico, four specially trained observers will take surface and upper-air observations. Eight additional smaller Coast Guard cutters in operation in the Gulf of Mexico have new precision meteorological instruments aboard with specially trained personnel for their proper observation.

Personalia

JOHN N. ADKINS, Director of Earth Sciences of the Office of Naval Research, has been named Chairman of the Division of Earth Sciences, National Academy of Sciences–National Research Council, to take the place of Harry H. Hess.

HARVEY O. BANKS, Director, California Department of Water Resources, has recently been awarded honorary membership in the American Water Works Association.

DETLEV W. BRONK, President of the National Academy of Sciences, President of the Rockefeller Institute for Medical Research, and Chairman of the National Science Board, has recently been made a foreign member of the Soviet Academy of Sciences.

J. CL. DE BREMAECKER will be on leave from the Institute for Scientific Research in Central Africa starting in August 1958. He will spend one year at Dunbar Laboratory, Harvard University, on a research fellowship.

JAMES J. DOLAND, Professor of Hydraulic Engineering at the University of Illinois, has recently retired after 32 years with the University.

JOHN G. FERRIS, Research Engineer, Ground Water Branch, U. S. Geological Survey, has recently been presented a Distinguished Service Award by the Department of Interior.

ALBERT G. FIEDLER, Assistant Chief, Water Resources Division, U. S. Geological Survey, has recently been awarded honorary membership in the American Water Works Association.

LAURENCE M. GOULD, President of Carleton College, has been elected President of Phi Beta Kappa for a three-year term.

HENRY W. HEMPLE, Captain, U. S. Coast and Geodetic Survey, retired, has been named the recipient of the 1958 Distinguished Service Award of the Alumni Association of Illinois Institute of Technology. Prior to his retirement in 1952, Captain Hemple was Chief of the Division of Geodesy.

J. W. HIGGINS, who served as District Geologist in the Exploration Department of the Standard Oil Company, has been designated Senior Research Geologist of the California Research Corporation on Oil Field Research.

FREDERICK L. HOTES of the Development and Resources Corporation, Ahwaz, Iran, has been given the J. C. Stevens Award of the ASCE for his discussion of the paper "Ground-water development—basin recharge."

JAMES H. KRAAKEVIK, Head of the Research Section of the Atmospheric Electricity Branch of the U. S. Naval Research Laboratory, has accepted an appointment as Assistant Professor of Physics at Wheaton College as of September 1, 1958. He will retain association with the Naval Research Laboratory as a part-time consultant.

J. LAURENCE KULP, Professor of Geochemistry and Head of the Geochemistry Laboratory of Columbia University, will spend the coming academic year at Oxford University as a National Science Foundation Senior Postdoctoral Fellow.

WALTER B. LANGBEIN, Hydraulic Engineer of the U. S. Geological Survey, has recently been given a Distinguished Service Award by the Department of Interior.

LUNA B. LEOPOLD, Chief Hydraulic Engineer, U. S. Geological Survey, has recently received a Distinguished Service Award from the Department of Interior.

DELBERT M. LITTLE, Deputy Chief of the U. S. Weather Bureau, retired on July 31, 1958, after more than 41 years of service.

MARTIN A. MASON, Dean of the School of Engineering, George Washington University, has been appointed to the Board of the Engineering Foundation which was established in 1914 to foster research in the science of engineering.

JOHN L. MERRIAM has recently returned from two years of duty as Senior Irrigation Engineer for the Division of Water Resources in the Ministry of Agriculture of Saudi Arabia to take up duties as Associate Professor of Irrigation at California Polytechnic College at San Luis Obispo, California.

ROBERT M. PAGE has been named Director of Research for Electronics in the Naval Research Laboratory.

JAMES A. PEOPLES, JR., has left his work as Head of the Terrestrial Sciences Laboratory of the Air Force Cambridge Research Center to take up duties as Associate Professor of Geophysics in the Department of Geology of the University of Kansas.

BARNEY J. PETERSON of the U. S. Geological Survey, retired, has recently received a Distinguished Service Award from the Department of Interior.

SVERRE PETTERSSEN, Professor of Meteorology at the University of Chicago, has recently received a Gold Medal Award from the American Meteorological Society for his contributions to the analysis of atmosphere and weather conditions.

TROY L. PEWE, formerly Geologist-in-Charge of the Alaskan Geology Branch, U. S. Geological Survey, College, Alaska, has recently been appointed Head of the Department of Geology at the University of Alaska.

GEORGE L. PICKARD, Professor of Physics at the University of British Columbia, has been appointed Director of the Institute of Oceanography at that University, succeeding W. A. Clemens who served as Chairman of the Committee on Oceanography since 1949 and was appointed as the first Director in 1954.

ROGER R. REVELLE, Director of Scripps Institution of Oceanography of the University of California, has been named Director of the University's new Institute of Technology and Engineering, located at La Jolla, California.

William W. Rubey, Geologist, U. S. Geological Survey, has recently been given a Distinguished Service Award by the Department of Interior.

Pierre St. Amand has taken a position with the International Cooperation Administration to help start a new school of Earth Sciences at the University of Chile in Santiago. He notes that the library in science is very fragmentary and appeals for contributions to the library in almost any field of science, requesting any who have contributions to make to write to him (U.S.O.M. Chile, United States Embassy, Santiago, Chile) and he will make arrangements to have them shipped at no cost to the donor and inscribed with the donor's name if he desires.

Allen H. Schooley of the Naval Research Laboratory has been designated as the new Associate Director of Research for Electronics, succeeding Robert M. Page.

Paul B. Sears of the Conservation Program of Yale University was recently awarded an honorary doctorate by Oberlin College.

H. Burr Steinbach, experimental zoologist and general physiologist, serving as Professor and Head of the Department of Zoology at the University of Chicago, has been designated as Chairman of the Division of Biology and Agriculture of the National Academy of Sciences–National Research Council. He succeeds L. A. Maynard of Cornell University. In his new capacity he will be a member of the Executive Committee of the AGU.

H. O'Reilly Sternberg, Director of the Center for Research in Geography of Brazil, and Professor of Geography at the University of Brazil, will serve as Visiting Professor of Geography at Indiana University during the second semester of the academic year 1958–1959.

B. Sundara Rama Rao, Professor of Geophysics at Andhra University in India, has taken up duties with the United Nations as an expert in Geophysics under the UNESCO Technical Assistance Program. He has been assigned the task of organizing postgraduate teaching and research in applied geophysics at Rangoon University in Burma.

Max Suter, Principal Engineer of the Illinois State Water Survey, retired September 1, 1958, after 22 years of service with the Survey.

William F. Uhl, President, Chas. T. Main, Inc., has been awarded the Rickey Medal for contributing "in an important manner to the science or progress of hydroelectric engineering."

Ernest H. Volwiler, President and General Manager of Abbott Laboratories, has been named Chairman of the Division of Chemistry and Chemical Technology, National Academy of Sciences–National Research Council, to succeed Frederick D. Rossini of Carnegie Institute of Technology.

George D. Whitmore, Chief Topographical Engineer for the U. S. Geological Survey, has recently been presented a Distinguished Service Award by the Department of Interior.

Fritz Zwicky of Mount Wilson and Palomar Observatories was one of the recent winners of prizes for the best essays on gravity awarded by the Gravity Research Foundation.

Willie O. Byrd of Northrop Aircraft, Incorporated, died July 6, 1958, at the age of 51. He was born in Augusta, Georgia, and took his baccalaureate degree from the Georgia Institute of Technology in 1927. He began his professional career with the Georgia State Highway Department as an engineer and took up duties in 1929 with the Walton Flythe Engineering Company in Georgia. In 1934 he established his own consulting firm and became a county engineer in 1935. From 1936 to 1946 he was in the Maps and Surveys Division of the Tennessee Valley Authority. Subsequently he did work in Guam and with the Mapping and Charting Research Laboratory of Ohio State University until 1953. Since this time he had been a specialist in research and development of reconnaissance systems for Northrop Aircraft. He had been a member of AGU since 1949.

Albert C. Hornady, Consulting Geologist in Amarillo, Texas, died July 5, 1957, at the age of 57. He took his baccalaureate degree from the University of Nebraska in 1930 and his master's degree from the same school in 1932. He began his professional career with the Phillips Petroleum Company and became their District Geologist prior to the establishment of his own firm in 1950. He had been a member of AGU since 1947.

Robert Larimore Pendleton of Kasetsart University in Bangkok, Thailand, died June 23, 1957, at the age of 66. He was born in Minneapolis and took his baccalaureate degree from the University of California in 1914 and his doctorate in soils chemistry in 1917. While working for his doctorate, he was assocated with the Soils Survey of California. He began teaching duties at Ewing Christian College in India in 1918, and took up duties with the Director of Agriculture, Gwalior State, India, in 1919, becoming Director in 1921. He then devoted several years to the teaching of soil technology at the College of Agriculture of the Philippines, where he continued until 1935. From 1935 to 1942, he was with the Department of Agriculture and Fisheries of Siam. In 1942, he became Principal Soil Technologist for the Office of Foreign Agricultural Relations, U. S. Department of Agriculture, and worked on various assignments in the Belgian Congo, the Far East, and South America, serving also during a part of this period as Professor of Tropical Soils and Agriculture at Johns Hopkins University. He had been a member of AGU since 1942.

Special Announcements

BACK *Transactions* OF THE AGU—Under arrangements with Walter J. Johnson, Inc. (111 Fifth Avenue, New York 3, New York), the stock of back *Transactions* of the AGU for 1955 has recently been turned over to that company for sale. The volume is still complete. Issues earlier than 1955, many of them fragmentary, were previously turned over to this company, whose affiliated company, the Johnson Reprint Corporation, is undertaking the reprinting of out-of-print back numbers. The first twelve volumes, through 1931, are now available from the company and others are in progress, their completion depending in some measure upon the demand that develops for these. Persons interested in these issues should write direct to the company rather than to AGU.

MEETING OF THE PACIFIC NORTHWEST REGIONAL GROUP—The Pacific Northwest Regional Group will hold its annual meeting in Portland, Oregon, November 13–14, 1958. The program for this year is built around the central theme of the International Geophysical Year. A feature of the meeting will be an address by Lloyd V. Berkner, Vice President of AGU and Vice Chairman of the International Committee for the International Geophysical Year. Interested persons should get in touch with the Chairman of the Regional Committee, Wilbur D. Simons (U. S. Geological Survey, 529 Perkins Building, Tacoma 2, Washington) or V. P. Schermerhorn, Secretary-Treasurer (U. S. Weather Bureau, 320 Custom House, Portland, Oregon).

MEETING OF THE AAAS IN WASHINGTON, D. C., DECEMBER 26–31, 1958—It is the plan that the American Geophysical Union will co-sponsor appropriate programs in the meeting of the American Association for the Advancement of Science held between Christmas and New Year's in Washington. Specifically included are a symposium on the subject of water and agriculture and sessions relating to the IGY.

PACIFIC SOUTHWEST REGIONAL MEETING TO BE HELD AT STANFORD, FEBRUARY 5–6, 1959—Attention is again called to this meeting, and plans for the program are developing rapidly. The Regional Committee has recently added to its membership Warren S. Wooster of Scripps Institution of Oceanography and J. F. T. Saur, Jr., of Stanford University especially to represent the field of oceanography. The other members of this Committee are: Vito A. Vanoni, Chairman; R. Corday Counts, Jr., Secretary; Eugene N. Bollay; Robert E. Holzer; Harlowe M. Stafford; and David K. Todd. Persons interested in participating in the program are asked to get into touch with the Program Chairman, Joseph B. Franzini, Civil Engineering Department, Stanford University, Stanford, California.

FORTIETH ANNUAL MEETING TO BE HELD IN WASHINGTON, D. C., MAY 4–7, 1959—As announced in the August issue of the *Transactions*, the Fortieth Annual Meeting will be held in Washington, D. C., Monday to Thursday, May 4–7, 1959. Plans of the various Sections are now getting under way, and it is anticipated that all Sections will have meetings. Also, there will be general meetings of the Union as a whole, including a Smoker on Monday evening, May 4, a general evening session including the Award of the William Bowie Medal on Tuesday evening, May 5, and a general session on Wednesday afternoon, May 6. Suggestions with respect to any of the Section or Union meetings are invited. Suggestions for the Union meeting should be sent to Philip H. Abelson, Chairman of the Committee on Meetings, AGU, 2801 Upton Street, N. W., Washington 8, D. C. For information regarding Section meetings, see list of Secretaries and Program Chairmen below.

This announcement will also serve as an invitation for members and others to send word of plans for papers to be presented. Titles of papers with three copies of the abstracts should be sent in as soon as possible and not later than February 20, 1959. Please give information concerning the time required (most papers are allowed from 10 to 20 minutes) and the projection equipment needed. This information should be sent to the office of AGU at 1515 Massachusetts Avenue, N. W., Washington 5, D. C., or to the Secretary or Program Chairman of the appropriate Section, as follows:

Geodesy, Frank L. Culley, Army Map Service, 6500 Brooks Lane, Washington 25, D. C., or Donald A. Rice (Program Chairman), U. S. Coast and Geodetic Survey, Washington 25, D. C.

Seismology, James A. Peoples, Jr., Department of Geology, University of Kansas, Lawrence, Kansas.

Meteorology, Woodrow C. Jacobs, 3812 Nash Street, S. E., Washington 20, D. C., or Max A. Eaton (Program Chairman), Office of Naval Research, Washington 25, D. C.

Geomagnetism and Aeronomy, Robert E. Gebhardt, U. S. Coast and Geodetic Survey, Corbin, Virginia

Oceonography, Donald W. Pritchard, Johns Hopkins University, Baltimore 18, Maryland.

Volcanology, Geochemistry, and Petrology, Lyman T. Aldrich, Department of Terrestrial Magnetism, 5241 Broad Branch Road, N. W., Washington 15, D. C.

Hydrology, Ralph N. Wilson, 3322 Stanford Street, University Hills, Hyattsville, Maryland, or Bernard Frank (Program Chairman), 2807 Washington Avenue, Chevy Chase 15, Maryland.

Tectonophysics, Benjamin F. Howell, Jr., Department of Geophysics and Geochemistry, Pennsylvania State University, University Park, Pennsylvania.

As Section Secretaries reserve the right to close filled programs in advance of the dates indicated, please make it a point to send word in early. Abstracts of the papers are published in the program. Remember that an abstract is an opportunity to bring the important results of your work to all those that see the program. The abstract should be concise but comprehensive and informative, and must not exceed 200 words. Longer abstracts will be reduced to 200 words or omitted at the editor's discretion. Complete manuscripts are not necessary but are desired and should be forwarded to the office of the Union by April 15 so that they will be available for science news writers. Please indicate whether the paper is being submitted for the program only or also for consideration for publication in the *Transactions*. If a paper is written in collaboration, please indicate by whom it will be presented. Arrangements can usually be made with the Section Secretary or Program Chairman for the presentation of papers by authors who are unable to attend, but papers to be presented by title only are not included in the program.

Make hotel or room arrangements directly with the hotel of your choice at an early date. If you fail on the first attempt, bear in mind that advance bookings that are not taken up are cancelled two weeks in advance and that a follow-up request in mid-April may bring the desired response. We are making block bookings at three hotels again; an announcement regarding these will appear in the Special Announcements in the December issue of the *Transactions*.

ELECTIONS OF OFFICERS IN 1959—Nominating Committees of the Union and the Sections are to report to the Executive Committee on October 18, 1958, concerning their nominations for officers for the triennium beginning July 1, 1959. A list of the nominees will be published in the December issue of the *Transactions*. In accordance with the regulations set up, nominees by petition may be added during January. See the December issue for details.

PUBLICATION PLANS FOR 1959—The ballot concerning publication plans recently placed before the membership has been tallied, 2081 voting in favor of the changes, 78 not in favor, and 46 ballots void. Accordingly, plans are progressing rapidly to institute the new monthly journal beginning in 1959. P. H. Abelson, Director of the Geophysical Laboratory of the Carnegie Institution of Washington, and James A. Peoples, Jr., Professor of Geophysics, Department of Geology, University of Kansas, have been appointed Co-Editors. Your attention is called to the four-page insert at the beginning of this issue which shows the tentative cover of the first number of the new journal. The inside front cover also appears about as it will appear in the journal. The succeeding two pages give more information on the publication plans. The *Transactions* will continue as a quarterly in 1959, containing word of activities of AGU, notes and personalia, and quasi-scientific material. Your comments are solicited.

TITLE PAGE FOR 1958 VOLUME—The title page for the 1958 volume is being carried in this issue of the *Transactions* (rather than the December issue) just preceding the Table of Contents.

NATIONAL ACADEMY OF SCIENCES

Number 15 • September 1958

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

The ARRL-IGY Propagation Research Project

This report is based on material supplied by Mason P. Southworth, ARRL-IGY Project Supervisior

Long-range, short-wave radio transmissions depend on conditions in the ionosphere, an electrified region of the atmosphere extending from approximately 45 to 250 mi above the earth's surface. The ionosphere contains several semi-permanent ionized layers which reflect most radio waves having wavelengths between 10 m and 10 km. Multiple reflection of a radio signal between ionospheric layers and the earth makes long-distance short-wave transmission possible.

The ionospheric layers are extremely variable with time and space and are extremely sensitive to the mood of the sun. The waxing and waning of solar activity during the eleven-year solar cycle is accompanied by changes in the reflectivity and other characteristics of the ionospheric layers. These changes may cause absorption of signals or propagation in unexpected directions or to unusual distances. They can be studied by analysis of a large number of radio contacts between distant points.

Propagation of radio waves occurs in a variety of ways, or "modes". The following paragraph describes briefly the modes under study in the IGY Propagation Research Program:

Radio waves travelling obliquely through the atmosphere may be scattered from inequalities in the ionosphere (*ionospheric scattering*); this provides transmission to distant points at frequencies for which the ordinary ionospheric reflection mechanism would not function. During sunspot maxima, ionospheric scatter is more extensive under the special ionospheric conditions which then prevail along paths crossing the equator (*transequatorial scatter*). Oblique incidence transmission may also be supported by reflection from clouds or patches of ionization in the E region (*sporadic E*), or by scattering from the long, thin ionization trails produced by meteors (*meteor scatter*). Another form of propagation arises by reflection from irregularities produced during auroras (*auroral reflection*). *Ground backscattering* occurs when a signal reflected from the ionosphere is scattered backward from the earth along the original path. Observation of all these modes of propagation yields information about the state of the ionosphere.

Outline of Program

During the IGY, the radio amateurs of the world are cooperating in recording data on v.h.f. (very high frequency) contacts by all modes of propagation affected by variations in the ionosphere. The US program is directed by the American Radio Relay League, Inc. (ARRL), under sponsorship of the US Air Force's Cambridge Research Center and the National Science Foundation. Large amounts of data are being gathered for the 50–54 and 144–148 megacycle amateur assignments, along with some information on 70, 220, and 420 mc.

Over 550 amateurs, or radio "hams," representing nearly 50 countries are taking an active part in the program, which is called the ARRL-IGY Propagation Research Project (PRP). They submit semi-monthly reports of the stations they contact or hear by means of the propagation modes described above. Nil reports are filed for intervals when the station is operative but nothing of interest is observed. A few of these stations maintain continuous, or "beacon," transmissions, and thereby give their fellow hams something definite to listen for.

Most amateur stations cannot supply precise quantitative data regarding signal strengths, azimuths, etc. They more than make up for this, however, by their extremely widespread distribution and by their enthusiastic approach, which has permitted amateurs to make the first use of virtually all known types of long-distance propagation. Through their efforts it should be possible to achieve an overall picture of worldwide propagation during the IGY that would be difficult to duplicate by any other means.

Reporting and Recording of Data

The report forms supplied to PRP observers call for: the date and the starting and ending times of the communication; the call sign and location of the other station; a rough idea of the signal's strength and fading rate and the direction from which it comes; the type of propagation the observer feels is responsible; and any pertinent comments. Such reports have been collected continuously since January 1, 1957, and will be collected through the end of the IGY. The six-months-early start served not only as a practice period, but also made it possible for much additional data to be collected as the sunspot cycle approached maximum.

As soon as all or nearly all of the reports for a given period have arrived at the PRP office, each entry on each form is carefully screened and evaluated according to propagation type and type of report. All items surviving this inspection are then transcribed onto special sheets in a partially coded form. Next, the latitude and longitude coordinates of each station (the observer's and the station he contacts or hears) are added to the sheets. To have this information available it has been necessary to maintain an up-to-date file concerning the locations of virtually all the several thousand amateur v.h.f. stations in the world.

At this point, the sheets go to an operator who prepares a punch card for each two-way contact report, heard report, negative report, and beacon report. A punch card presentation was chosen for the PRP data because it lends itself so well to high-speed automatic handling of the large quantities of information being gathered. During the twelve months of 1957, an average of more than 9600 cards per month were required to document the report items. The number will probably be somewhat higher in 1958; card punching and verifying for May has just recently begun. Peak reporting occurs during the early summer months, when sporadic-E propagation on 50 mc is at a high.

Once punched and verified, the cards for each month are put into chronological order and sorted out according to type of propagation. Cards reporting two-way contacts are examined for duplications—that is, two cards may be submitted for one contact when both stations are PRP observers. One card from each such duplicate pair is removed from the file and the other is punched to show it is a "confirmed" report.

At the present time, cards listing negative and beacon reports are being kept on file at the PRP office, while those citing positive results go to the Air Force Cambridge Research Center for further processing. This consists of preparation of a duplicate deck of cards plus the machine-computation of path lengths and midpoint coordinates for the single-hop sporadic-E reports and ionospheric forward-scatter reports. Listings of the single-hop sporadic-E reports are now being transmitted to the IGY World Data Center as soon as computations for each period are complete.

Another machine program has been evolved for determining the reflection point for auroral propagation, using the locations and antenna headings of the reporting stations. Due to the relatively small number of cases in which heading information is available from both ends of the path, however, this program has not yet been used.

Other Aspects of Program

Other work being done includes the publication of a monthly bulletin, *The PRP News*, which is circulated among the observers. This provides a brief summary of the preceding month's reports as well as other informational and instructional material of interest to radio amateurs. There is also an award system in which observers earn a certificate plus endorsement stamps for consistent reporting.

Further Uses of Data

There are a great many possible uses for this program's data after the IGY. The documentation of auroral and sporadic-E conditions has been particularly complete and should be of great value in investigations of these phenomena. In the case of transequatorial-scatter propagation, PRP reports have even more potential worth. Not only has much information been gathered for the Central and South American paths first noted by amateurs during the last sunspot maximum, but similar work has been done for the first time between Japan and Australia and between southern Europe and the Rhodesias. These additional circuits should help provide an insight into the seeming location selectivity of transequatorial propagation.

IGY stations operating in Chile and Peru under the direction of the National Bureau of Standard's Central Radio Propagation Laboratory have been of special help. These have been monitored by the amateur observers, and have been received in the United States and southern Canada with surprising consistency and with surprisingly variable fading and strength characteristics during the equinoctial periods.

Although punch cards have not been prepared for the F2-skip reports, they, together with the backscatter data, should furnish the actual highest usable frequencies over many varying paths for comparison with the predicted values and with those observed by other means.

The work of the hams has proved its worth many times in the past. It is expected that the ARRL-IGY Propagation Research Project will help fill a gap by making a large volume of amateur reports available to investigators in an easily usable form.

Weather at US-IGY Antarctic Stations During 1957

The following material was supplied by Edwin C. Flowers, meteorologist, US Weather Bureau.

The year 1957 was the first complete year of operation for most of the United States IGY stations in Antarctica. It was also the first year in history during which enough meteorological stations were in operation to give a synoptic picture of Antarctic weather.

Although it is much too early to answer the fundamental meteorological questions posed by the Antarctic environment, the observations made at US stations recorded facts about Antarctic surface and upper-air weather that had never before been documented. Highlights of the weather observations at each of the stations are given below.

IGY Little America Station

At IGY Little America Station, the year 1957 was warmer than any of the five previous years for which records are available (Table 1).

The extreme cold temperature recorded during 1957 (−53°C) was also considerably warmer than the absolute minimum over the period of record (−61°C), observed in 1956.

The past year was one of striking weather changes. Storms in June (a mid-winter month) gave that month an unusually warm average temperature. Thus, the June average of −23.9°C made it the warmest month since February. It was 7° warmer than May and nearly 12° warmer than July (see Fig. 1). The most sustained storm in June lasted, nearly without interruption, from the 13th through the 21st. On the 14th, the average wind speed for the day was 42 mph, with an average temperature of −8°C. The peak gust was 59 mph. As in nearly every case of strong winds at Little America Station the wind direction was from the NNE. During the stormy period, the temperatures rose rapidly with the increase in wind speed. Prior to the commencement of the storm, the minimum temperature was −46°C, while during the period June 13–21, the maximum temperature was −4°C and the minimum was −23°C. On the day following the cessation of the extreme winds, the temperature dipped to a minimum of −32°C.

This pattern of warming temperatures with strong winds is a normal feature in the Antarctic due primarily to mixing of the air in the inversion layer. The inversion layer consists of a stratum of air, from the surface to perhaps 500 m to 1000 m above the surface, throughout which the temperature rises with increasing altitude. At Little America Station in winter, the top of the inversion may be as much as 10–25°C warmer than the air next to the surface. An increase in wind speed in this layer causes turbulent mixing and a subsequent warming of the near-surface air.

Table 1. *Little America (and Framheim,* 1911): Average Annual Temperatures (°C)*

1911	1929	1934	1940	1956	1957
−27.2	−26.4	−25.7	−26.2	−25.1	−24.2

* Amundsen's camp. Near the present location of Little America Station.

The absolute minimum temperature for the year (−53.0°C) was recorded on May 24. The month of May also produced the warmest temperature ever recorded for that month (−1.0°C on the 11th). This was the greatest temperature spread for any month in 1957.

The average wind speed for the period April-September was 15 mph, while for the remaining six months the average was 12.5 mph. The sea-level pressure ranged from a high of 1030 mb on June 10 to a low of 931 mb on August 29. From January 30 through December 31, a total of 644 rawinsonde flights were made. The average height during the months April-September was 18.8 km; for the remaining months it was 21.3 km.

IGY Byrd Station

Nearly continuous storminess was the significant feature of the weather at Byrd Station during July, August, and September, 1957. These three months had average wind speeds of 22, 27, and 26 mph respectively. During August, ten days had daily average speeds greater than 30 mph and six days had average speeds greater than 40 mph, while only two days had average speeds less than 15 mph. Nearly all of the strong winds came from a northerly direction, usually with an easterly component. During most of the periods of storminess, the northerly winds were consistent throughout the troposphere above Byrd Station. They usually reached near jet velocities between 8 and 10 km above sea level. With strong winds, blowing snow becomes a hazard. During

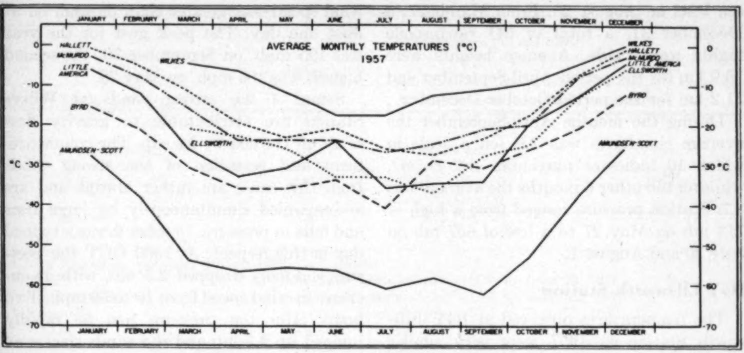

Fig. 1. *Average Monthly Temperatures for US-IGY Antarctic Stations and the Air Facility at McMurdo Sound During 1957.*

August, visibility was reduced to a quarter of a mile or less for this reason on four out of five days.

Despite the high incidence of strong winds, the station maintained an excellent record of rawinsonde flights. From March 23 through December 31, a total of 510 rawinsonde flights were made. Average heights were 16.4 km for the period April-September and 22.7 km for the period October-December. As at other high latitude Antarctic stations, minimum stratospheric temperatures in the range of −80°C to −90°C were a feature of the upper atmosphere during the three winter months. The yearly range of station pressures for 1957 was from a high of 833 mb on May 13 to a low of 775 mb on July 30 and December 9.

IGY Amundsen-Scott Station

Quite different weather prevailed at the Pole Station, where only one significant storm was observed. This occurred May 25–29, with wind speeds in the range of 25–50 mph. With the onset of this storm, the temperature rose from −69°C, with a 14-mph wind, at 0900 GCT to −46°C, with a 40-mph wind, 24 hours later. Only a few gusts greater than 40 mph were observed during the remainder of the year. However, winds of moderate speed prevailed nearly constantly throughout the winter months, producing for the period April-September an average speed of 18 mph. During June, of the 720 hourly wind speeds measured, 95% were in the range of 13–29 mph; of the remaining 5% of the hourly records, 4% were in the range 7–12 mph and 1% greater than 30 mph. No hourly winds of less than 7 mph were recorded during the month. The peak gust for the year was 54 mph, measured on May 25.

Throughout the winter, the surface inversion averaged 25°–30°C, with the top in the vicinity of 500 m above the surface. An extreme inversion of 41°C within 700 m occurred at 0600 GCT on September 18.

With the return of the sun, rawinsonde observations began to give indications of a rapid warming in the stratosphere. At 25 km, temperatures rose from −67°C to −24°C from the 1st to the 30th of October. This warming gradually became apparent in the troposphere, so that by mid-December miniumum temperatures measured in the upper air were in the range −45° to −50°C. The lowest temperature measured in the stratosphere was −91.2°C at 17.7 km above sea level on August 20. From March 27 to December 31, a total of 541 rawinsonde flights were made. Average heights were 16.9 km for the period April-September and 21.2 km for the period October-December.

During the months April-September the average cloudiness was 2.6 (on a scale in which 10 indicates maximum sky cover), while for the other 6 months the average was 4.7. Station pressure ranged from a high of 713 mb on May 27 to a low of 657 mb on July 30 and August 1.

IGY Ellsworth Station

The temperatures observed at IGY Ellsworth Station in 1957 were very similar to those observed at Little America Station as far as averages and extremes are concerned. The absolute minimum temperature for 1957 (−53.3°C) occurred on May 10. It is of interest to note that the synoptic weather situation that produced the Ellsworth Station minimum was at the same time bringing record cold (−73.6°C) to the Amundsen-Scott Station and record warm temperatures to Little America Station (−1°C) and to Byrd Station (−6.9°C).

The average wind speed for the months April-September was 14 mph; the prevailing wind direction was south for 5 of the 6 months. For the remaining 6 months, the average speed was 10 mph, also prevailing from the south. The peak gust for the year of 63 mph occurred on May 24. High and low station pressures for the year were 1014 mb on August 10, and 957 mb, on July 22. Between April 1 and December 31, a total of 496 rawinsonde flights were made.

IGY Wilkes Station

Wilkes Station experienced the warmest climate of the seven United States stations and, although not the windiest as far as averages go, it had the highest incidence rate for gale-force winds. In the month of August, wind speeds exceeded 58 mph on 13 days, although the average speed for the month was only 15 mph. During each of the 10 months of record for 1957, the wind speed was greater than 55 mph on at least one day. The peak gust for the year was 105 mph, on September 30; the second highest was 100 mph, on May 28.

Some of the strong winds at Wilkes Station are attributable to gravity flow of air off the nearby ice cap. The commencement and cessation of the strong winds from this cause are rather abrupt and are accompanied simultaneously by large rises and falls in pressure. October 9 was a typical day in this respect. At 1500 GCT the pressure suddenly dropped 2.5 mb, with an increase in wind speed from 10 to 50 mph. Two hours later the pressure just as rapidly jumped up 3.5 mb and the winds slackened to 10 mph. Although the prevailing winds are ESE (off the ice cap), the gravity flow only occasionally reaches these extreme speeds. Apparently, the location and height of the surface inversion with respect to the station is an important factor in the incidence of these strong winds.

During the month of December, rawinsonde flights at Wilkes Station were as follows: Of the total of 61 flights made during the month, 60 reached or exceeded the 50-mb pressure level (20.6 km above sea level); moreover, 56 of these reached or exceeded the 25-mb pressure level (25.6 km above sea level). The average termination height for this month was 26,992 m.

The minimum temperature for the year (−33°C) was recorded on July 24. For each month, with the exception of July and September, the maximum temperature reached 0°C or higher. The sea-level pressure ranged from a high of 1019 mb, on May 23, to a low of 951 mb, on September 10.

An ice-cap station, some 50 mi ESE of the main camp and at an elevation of about 1310 m, provided additional meteorological data for this region. At the ice-cap station, temperatures averaged about 10°C lower than those at the main camp. The minimum temperature of −48.2°C was measured on June 14. The average wind speed was about 25 mph, with a prevailing wind direction of ESE.

Table 2. *Averages and Extremes of Temperatures at US-IGY Antarctic Stations in 1957*

Station	Temperatures (°C) and Dates		
	Average	Max.	Min.
Little America	−24.2	+4.4 Jan. 3	−53.0 May 24
Byrd*	−27.6	−4.4 Nov. 29 Dec. 26	−56.9 June 11
Amundsen-Scott*	−48.7	−18.9 Dec. 15	−74.5 Sept. 17
Ellsworth*	−22.3	+1.8 Nov. 25	−53.3 May 10
Wilkes*	−8.1	+6 Dec. 20 Dec. 21	−33 July 24
Hallett*	−15.1	+4.0 Dec. 13	−42.0 Aug. 3
NAF McMurdo*	−16.7	+3.4 Dec. 23	−41.1 Aug. 2

* New extremes recorded during 1958, as follows:

Byrd	minimum temperature −59.7 on June 16, 1958
Amundsen-Scott	maximum temperature −14.7 on Jan. 12, 1958
Ellsworth	minimum temperature −55.6 on May 13, 1958
Wilkes	maximum temperature +8 in Jan. 1958
Hallett	maximum temperature +5.7 on Jan. 15, 1958
McMurdo	maximum temperature +4.4 on Feb. 4, 1958

IGY Hallett Station

Low-pressure systems moving past the station on their way into the Ross Sea area provided the Hallett Station with its most interesting weather. The annual temperature regime, with respect to monthly averages, was very similar to that observed at many other Antarctic stations, with a rapid drop in April and May, followed by warming in June, and another minimum in July and August.

The average wind speed for the months April-September was 9 mph; for the other 6 months the average was 10 mph. Prevailing direction was SW for 7 months and SSW for the other 5 months. The maximum gust measured was 114 mph, on October 23; two other months had days with wind speeds in excess of 85 mph. The storm of mid-October, which produced the 114 mph gust, interrupted a continuous series of 246 rawinsonde flights begun on June 23. The sea-level pressure ranged from a high of 1027 mb, on May 28, to a low of 955 mb, on July 23.

NAF McMurdo

The Naval Air Facility, at the foot of Observation Hill on Ross Island, McMurdo Sound, had its share of blizzard weather. During each month from May through November, maximum wind speeds of 65 mph or greater were recorded on at least one day. May had a peak gust of 96 mph, while a peak of 97 mph was measured in June. The average temperature for the months April-September was −23.9°C; the other 6 months had an average of −9.4°C. The sea-level pressure ranged from an absolute high for 1957 of 1041 mb, in May, to a low of 949 mb, in August.

During the period April-December 1957, 68% of the scheduled rawinsonde observations reached or exceeded the 50-mb pressure level and 19% reached or exceeded the 25-mb level. During September 1957, 51 observations (or 85%) reached or exceeded the 50-mb pressure level; 21 observations (or 35%) reached or exceeded the 25-mb level.

Table 2 lists the annual average temperatures and extremes during 1957 for the seven US-IGY stations (including the joint New Zealand-US Hallett Station). For the Wilkes and Ellsworth Stations, the period used to compute the annual average was March 1957 through February 1958. Figure 1 is a plot of the average monthly temperatures (°C) for the same seven stations.

Fourth US-IGY Satellite

The fourth US-IGY scientific earth satellite, 1958 Epsilon, was launched in a northeasterly direction from Cape Canaveral, Florida, a few seconds after 11:00 am EDT July 26, 1958. A little more than six minutes later the satellite, also known as Explorer IV, entered into an orbit which will cover an area between 51°N and 51°S latitude (see Fig. 2), as compared with approximately 34° for 1958 Alpha and Gamma. The launching vehicle was identical to those used for 1958 Alpha and Gamma except for an increase in thrust in the high-speed upper stages; the vehicle was developed jointly by the US Army Ballistic Missile Agency and the California Institute of Technology's Jet Propulsion Laboratory.

Satellite Characteristics: The steel satellite is 80 inches long, 6 inches in diameter, and weighs 38.43 lbs, about 7½ lbs heavier than its predecessors. Like 1958 Gamma, it does *not* carry a turnstile antenna with its four whip-like extensions; 1958 Epsilon's two dipole antennas utilize the skin of the satellite itself.

Instrumentation: 1958 Epsilon carries two Geiger-Mueller counters and two scintillation counters designed to measure corpuscular radiation at several levels of intensity. 1958 Epsilon's total concentration on corpuscular radiation studies was prompted by data obtained from the earlier Explorer satellites. This had suggested the existence of radiation of a very high intensity at altitudes greater than about 1000 km (about 600 mi).

The instrumentation on 1958 Epsilon was designed and developed by Carl E. McIlwain and George H. Ludwig of the State University of Iowa, under the direction of James A. Van Allen, head of SUI's Physics Department. The four detectors were developed by McIlwain, and are linked to an electronic system of measuring, scaling, and amplifying devices; the overall scientific package was engineered by Ludwig.

One of the Geiger-Mueller counters, shielded with 1/16 of an inch of lead, measures absorption of X-radiation and counts intensities of the more penetrating cosmic

rays. The other counter has been scaled to handle some 1500 times the radiation intensity that caused the detection and scaling systems of 1958 Alpha and Gamma to blank out (see *Bulletin No. 13, July 1958*).

Scintillation counters use crystals of selected materials mounted directly on the faces of sensitive photoelectric cells, usually of photomultiplier type. The scintillators emit flashes of light when radiation passes through them. The resulting light pulses are converted into electric pulses by the photomultiplier.

One scintillation detector in Explorer IV makes use of a lightly-aluminized crystal of cesium-iodide as a scintillator. The integrated electric current from its photomultiplier provides an approximate measure of the total energy of the incident corpuscular radiation. A second scintillation detector utilizes an aluminized plastic scintillator and acts as a counter of incident corpuscular radiation.

1958 Epsilon carries two radio transmitters. The low-power transmitter operates on 108.00 megacycles at 10 milliwatts, the high-power transmitter on 108.03 mc at 30 mw. The battery life for each is expected to be about two months. Both transmitters broadcast the same five channels of telemetered information continuously, although the low-power transmitter is primarily for tracking purposes.

Tracking: Besides the Naval Research Laboratory's usual Minitrack network (see *Bulletin No. 2*), ten Microlock stations are tracking the satellite and recording its telemetered data. The stations are located at Cape Canaveral, Florida (JPL); Fort Monmouth, N. J. (Army Signal Corps); Van Buren, Maine (Army Signal Corps); Aberdeen Proving Ground, Md. (Ballistic Research Laboratories); White Sands, N. M. (BRL and JPL); Cedar Rapids, Iowa (Collins Radio Company); Temple City, Cal. (San Gabriel Valley Radio Club); China Lake, Cal. (Naval Ordnance Test Station); and Goldstone Test Station, Camp Irwin, Cal. (JPL).

The first precision photograph of the satellite was secured by the Baker-Nunn satellite tracking camera at Arequipa, Peru, at 12:53 am Universal Time, July 28, 1958. More than 230 Moonwatch teams were also in action. The first visual sightings of 1958 Epsilon by a Moonwatch team took place in Pretoria, Union of South Africa, at 3:20 am UT, July 29, 1958. The satellite was sighted by Roy Smith, who heads the Pretoria team.

Orbit: The Naval Research Laboratory reported the orbit of 1958 Epsilon, as of July 29, 1958, as: Period, 110.224 minutes; inclination of orbit to the equator, 50.13°; perigee, 157.3 statute mi; apogee, 1379.8 statute mi; velocity at perigee, 18,406 mph; and velocity at apogee, 14,232 mph.

Early Results

Preliminary results from about one-fourth of 1958 Epsilon's first 200 passes have been reported by State University of Iowa staff. They indicate that the intense radiation measured by 1958 Alpha and 1958 Gamma is not X-radiation originating within the satellite through bombardment of the satellite's skin by solar electrons, as believed at first. The data show, instead, that the Geiger-Mueller and scintillation counters in the satellite are being struck directly by high-energy charged particles, probably electrons. These may include hydrogen protons or other atomic fragments that have lost some of their electrons.

At least 60% of the charged particles readily penetrate the lead shielding one of the satellite's geiger tubes. The radiation intensity appears to double with each 60 mi above 250 mi., at least to Explorer IV's maximum altitude. According to SUI physicists, the satellite has found a radiation level of about 10 roentgens/hr at a height of 1200 mi above South America. This is more than 100 times the saturation level of the geiger tube in 1958 Gamma.

Cosmic Ray Program: First Twelve Months

This report is based on a summary of results in the IGY Cosmic Ray Program prepared by Scott E. Forbush, Department of Terrestrial Magnetism, Carnegie Institution of Washington.

Cosmic rays are extremely high-energy electrically-charged particles that continually bombard the earth from all directions. They attain their high energies—ranging from about 100 million to 10 billion billion electron volts (10^8 to 10^{19} ev)—within our galaxy. On rare occasions, our sun also produces charged particles with cosmic ray energies that reach the earth.

The primary cosmic rays reaching the earth's atmosphere consist almost entirely of protons (approximately 90%) and heavier nuclei. Their interaction with atmospheric particles creates "showers" of secondary particles. These include secondary protons and nucleons, pi mesons (charged and neutral), and heavier mesons.

Neutral pi mesons disintegrate into two gamma rays; these are ultimately transformed into electrons and photons and contribute to the soft (low-energy) component of cosmic rays. At surface level, this contribution to the low-energy component is small.

Charged pi mesons commonly disintegrate, forming charged mu mesons. The charged pi mesons that do not have time to decay before interaction with the atmosphere may cause new electron-nuclear showers, or nuclear fission disintegrations of the star type observed in emulsions.

Charged mu mesons constitute the high-energy, or hard, component of cosmic rays. Changes in intensity of the charged mu mesons are measured by heavily shielded ionization chambers and by heavily shielded counters.

Neutron monitors, on the other hand, are more sensitive to variations arising from changes in the intensity of the much lower energy primaries. For example, they indicate a latitude variation ten or more times greater than measured by shielded ionization chambers. In a neutron monitor, the cascade of atmospheric nucleons generates neutrons locally in the lead of a lead-paraffin pile. The paraffin slows down these neutrons to thermal energies; this increases the probability that they will be captured by the Boron-10 nuclei in the $B^{10}F_3$ gas used in the counter. After capture, the Boron-10 disintegrates into a lithium nucleus and an alpha particle. The 2.5 mev energy of these particles produces a pulse of ionization to trigger the counting circuit.

The fact that the IGY was scheduled for a period of maximum solar activity is of particular benefit to cosmic ray research. A number of significant advances have already been made in our understanding of cosmic rays and their causes, effects, and interrelationships with other phenomena. The following is a summary of some advances in cosmic ray knowledge by US investigators through the first 12 months of IGY.

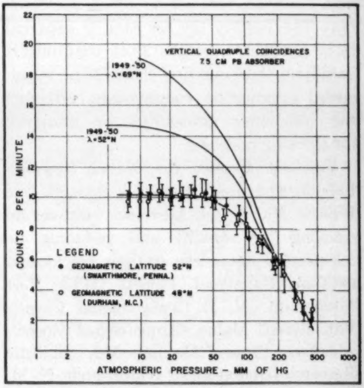

Fig. 3. *Variation of Cosmic Ray Counting Rates With Height at Geomagnetic Latitudes 52°N and 48°N. Data for geomagnetic latitude 52°N were gathered on three separate balloon flights; data for 48°N were gathered on four flights.*

Variations with the Solar Cycle

IGY scientists, using a variety of techniques, find that the beam of cosmic ray particles coming principally from the galaxy and arriving at the earth has drastically changed between the last minimum of solar activity (1954) and the present solar maximum (1957–58).

Mu-Meson Intensity: S. E. Forbush of the Department of Terrestrial Magnetism, Carnegie Institution of Washington, is supervising a long-term experiment involving continuous registration in ionization chambers of the mu-meson component of cosmic radiation. This work has continued over a period of two solar cycles and the records represent the longest continuous chain of cosmic ray data published. The results show an 11-year cycle of intensity variations roughly opposite in phase to that of sunspot numbers, but lagging about one year behind the sunspot numbers. Since the IGY is near a peak in the solar activity cycle, cosmic ray intensity is now relatively low.

The range of this variation in terms of monthly means is about 6%, as measured at Cheltenham, England; Huancayo, Peru; Christchurch, New Zealand; and Godhavn, Greenland. The variability of daily means from monthly means for 1957 was considerably greater than during the two previous sunspot maxima. Study of these variations in the mu-meson component of cosmic rays provides information on changes in the flux of relatively high-energy primaries.

Neutron Intensity: The solar-cycle variation is also exemplified by measurements made between 1954–55 and the first part of 1958 by J. A. Simpson and his colleagues of the University of Chicago. They found a decrease of 25% in neutron intensity at Climax, Colorado. They also showed that the ratio of neutron intensity at Climax to that at Huancayo decreased from about 1.25 in 1954 to about 1.08 in 1958, thus demonstrating a strong energy dependence on the 11-year intensity variation. Latitude surveys with neutron equipment in aircraft showed the proton integral-energy spectrum to be about E^{-2} in 1948 and in 1958, and about $E^{-2.7}$ in 1954. (The observed flux of particles arriving is proportional to the particle kinetic energy, E, raised to the indicated power.) On the basis of balloon flights between 1953 and 1958 it was shown that the 25% decrease in neutron intensity at Climax represents more than a twofold decrease between 1954 and 1958 for particles with energies of 1 bev or greater.

Ionization: IGY balloon flights carrying ionization chambers were made in 1957 at Thule under the direction of H. V. Neher, of the California Institute of Technology (see *Bulletin No. 11*). It was found that the ionization at an atmospheric pressure level of 15 gm/cm² (93,500 ft) was only half that in 1954, and that the number of primary particles had diminished by a factor of four. Similar observations at Thule in 1955 and 1956 showed that the intensity decrease followed closely an increase in sunspot numbers.

Vertical Particle Flux: A series of balloon soundings were made by J. R. Winckler and L. Peterson of the University of Minnesota in August-September 1955 at geomagnetic latitude 51.2°N to 64.2°N, and IGY flights were conducted at geomagnetic latitudes near 51.2°, 55.3°, and 58.6°N in June 1957, immediately prior to the beginning of the IGY. It was found that near the sunspot maximum in 1957–58 the vertical particle flux had decreased at all atmospheric levels greater than 300 gm/cm² (33,000 ft). It was also found that the magnitude of this decrease became greater with increasing height until, at high altitude and high latitude, it reached nearly a factor of two. These experiments showed that of the additional particles admitted at 10 gm/cm² (102,000 ft) in 1955 between geomagnetic latitudes 51.2°N and 58.6°N, at most only one-sixth remained in 1957, and that the relative latitude effect in this range was reduced from 40% to 10% or less.

Latitude Knee: With simultaneous balloon flights at geomagnetic latitudes 48°N and

52°N, near May 1, 1958, M. A. Pomerantz of the Bartol Research Foundation showed the variation with atmospheric height of the vertical quadruple-coincidence counting rate to be the same at both latitudes (see Fig. 3). (A quadruple-coincidence instrument is one that records the passage of those cosmic ray particles which trigger four separate, successive counters, thus indicating the angle of entry of the particle.) This indicated that the "knee" of the latitude effect—the latitude at which cosmic ray intensity ceases to increase with increasing latitude, represented graphically by a bend, or "knee," in the curve—was then south of 48°N. Similar observations in 1949–1950 showed no evidence of a true primary knee south of geomagnetic latitude 60°N.

Nucleonic Component: John A. Lockwood, of the University of New Hampshire, reports that from July 1954 to December 1957 the monthly mean intensity of the nucleonic component of cosmic radiation measured at Mt. Washington, New Hampshire—geographic latitude 44.2°N, elevation 6262 ft—decreased by 22%. The lowered intensity now prevailing came about through a series of sudden decreases. The largest of these occurred in February and November, 1956, and in January and September, 1957. After these decreases, the intensity recovered only partially. This long-term variation was accompanied by an increased number of day-to-day intensity changes.

Rapid Decreases During Magnetic Storms

During the past several years, it has become clear through the work of US investigators that the intensity of the cosmic radiation reaching the earth undergoes large changes with time, and that these changes are associated with electromagnetic phenomena on the sun. Phenomena that produce large changes in the cosmic ray intensity at the earth have become the central problem of interest. Not only does their study add to an understanding of cosmic ray and solar effects, but analysis of this data is leading to knowledge of magnetic fields in interplanetary space and to explanation of many magnetic storm effects at the earth's surface.

In 1957, large decreases in cosmic-ray intensity during magnetic storms were unusually numerous. Several US investigators have recorded large variations in daily mean neutron intensity for various intervals during the IGY. The sudden decrease in daily mean neutron intensity from August 29 to 30, 1957, was between 8% and 10% at IGY stations operated by the Universities of California and Chicago and the Bartol Research Foundation, Pennsylvania. This is about 2.5 times the change in ionization at Huancayo.

R. B. Brode, University of California, has reported daily means of neutron intensity at Berkeley and Hawaii for the period July 1, 1957–March 31, 1958. There is a good correlation between variations at these stations; variations are smaller at Hawaii, however, undoubtedly owing to the difference in geomagnetic latitude (see Fig. 4).

M. A. Pomerantz, Bartol Research Foundation, reports that values of daily means of neutron intensity at Thule (August 20, 1957–March 31, 1958) correlate well with values obtained by D. C. Rose at Ottawa and Resolute, Canada. Using balloons on several days between August 21 and September 18, 1957, Pomerantz also measured the vertical quadruple-coincidence rate under 7.5 cm Pb at altitudes above the 28 gm/cm^2 (80,000 ft) pressure level. These results show a decrease of about 20% near September 1 as compared with August 20.

Twelve-hour neutron-intensity means at Chicago from July 22 to September 1957 reported by Peter Meyer showed a range of nearly 20%. Meyer has also conducted balloon flights in Canada on days when the neutron intensity at Chicago differed, from one to another of these days, by 12%. His purpose was to determine whether the change in proton and alpha-particle flux is different at these two locations.

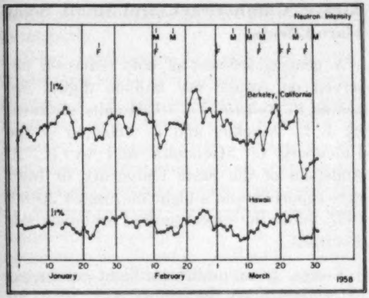

Fig. 4. *Comparison of Daily Means of Neutron Intensity at Berkeley, California, With Daily Means at Hawaii.* (*M = magnetic storm; F = solar flare*)

Flux of Alpha Particles and Heavy Particles

Investigation of the flux of the alpha-particle and heavy-particle components of cosmic rays is providing additional knowledge of the time scale of fluctuations of cosmic rays, their behavior at higher energy levels, and the variation of the heavier charge components of the primary particles with respect to solar activity.

Alpha-Particle Flux: P. S. Freier, E. P. Ney, and C. J. Waddington, of the University of Minnesota, report several determinations of the flux of primary cosmic ray alpha particles made during the past few years at high altitudes over Minnesota and over Texas. In an appreciable number of these determinations, small stacks of nuclear emulsions were carried aloft by balloons for use as detectors.

In such a flight made just prior to the IGY, Freier and Ney found that the flux over Minneapolis had fallen from its previous value of about 280 alpha particles/$m^2 \cdot$ster$\cdot$sec (the number of particles passing through a one-square-meter area each second from directions lying within a unit solid angle, or steradian) to a value a little more than half that. A flux value of 138 ± 9 alpha particles/$m^2 \cdot$ster$\cdot$sec was determined; another stack, exposed at the same place some 3½ months later, indicated that this decrease was not a transient effect.

The latter flight was made during a large Forbush decrease. While there does not appear to have been a significant difference between the total fluxes observed in the two stacks, there was a significant reduction of low-energy particles. In the first stack, the flux of alpha particles with energies below 700 mev/nucleon was 47 ± 8/$m^2 \cdot$ster$\cdot$sec (the old value was 120 ± 10), while in the second stack it had fallen to approximately one-half this value.

Yet another flight made about 1½ months later over Texas, where the cut-off energy is approximately 1.5 bev/nucleon, showed that the flux of these high-energy particles had declined by about one-third from the previously measured value of 97 ± 8/$m^2 \cdot$ster$\cdot$sec.

In each of these stacks, the energies of the low-energy alpha particles were determined from a measurement of their ionization, using a photodensitometer.

In addition to the ionization measurements, energy determinations were made from multiple-scattering measurements on about half the alpha particles observed in the second stack exposed over Minnesota. These suggest that the present integral-energy spectrum is not as steep as it was previously, and that the new flux obtained over Texas agrees closely with that predicted from the Minnesota measurements.

H. Yagoda has reported measurements of the time variation of the omnidirectional flux of heavy primaries, as obtained by small emulsion blocks exposed in rockets at geomagnetic latitude 41°N between December 1952 and October 1957. The experiments were carried out with the cooperation of GRD-AFCRC. They show a 10–20% diminution in intensity roughly coincident with a period of maximum sunspot activity, in 1957 (see Fig. 5). The small effect at low geomagnetic latitudes parallels more pronounced variations both in the total ionization and in the alpha-particle

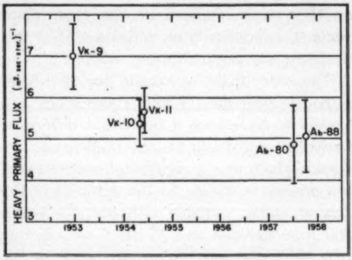

Fig. 5. *Decrease in Omnidirectional Flux of Heavy Primaries, 1952–58, at Geomagnetic Latitude 41°N. Vk numbers represent flights using Viking rockets; Ab numbers, Aerobee flights.*

flux at geomagnetic latitude 55°N during the same period, as indicated by exposure of emulsions near maximum balloon altitudes (about 100,000 ft). Yagoda suggests that the heavy primary component of the cosmic radiation follows time variations related to the solar cycle.

Proton and Alpha-Particle Time Variations: Using a simplified combined scintillation and Cerenkov counter on balloon flights over Prince Albert, Canada, the time variation of the protons and alpha particles was measured separately by Peter Meyer of the University of Chicago. A detailed analysis has been completed only for the flights on August 30 and September 16, 1957. While the neutron intensity at Climax was 12% greater on the latter date than on the former, the proton intensity over Prince Albert was 16% greater and the alpha-particle intensity 25% greater. Meyer feels that these results are consistent with a common modulating mechanism for protons and alpha particles. On both flights, the alpha-particle flux seemed to increase appreciably during the eight hours the equipment was at altitude without a corresponding change in proton intensity. These independent changes in alpha-particle and proton intensity cannot be accounted for by any modulation mechanism so far considered.

X-rays, Gamma-rays, and Small Solar Flare Effects

A general account of soft radiation observed on cosmic ray balloon flights appeared in *Bulletin No. 10*. Results obtained by J. L. Winckler and L. Peterson of the University of Minnesota and by K. A. Anderson of the State University of Iowa were reported, and a flight on August 29–30, 1957, under the supervision of Anderson was described.

X-rays: In an additional flight conducted by Anderson on September 1–2, 1957, an X-ray shower not associated with a magnetic storm, as in the August 29–30 event, was observed. The radiation was present even before the balloon reached ceiling altitude, at 1420 UT, and was still detectable 12 hours later. After some early time variations, the radiation slowly diminished in a roughly linear fashion. The ion-chamber to single-counter ratio changed very markedly (more than threefold) during the flight, particularly during the first hour after ceiling altitude was reached. The ratio became so high at times that there appeared to be no way to attribute the radiation to X-rays. During the greater part of the event the ratio was characteristic of 100-kev X-rays, although ratio evaluation becomes inaccurate as the X-ray intensity diminishes.

It was established on several night flights made while the regularly appearing auroral forms were present that these forms contributed a small quantity of soft radiation at the altitude of the balloon.

The University of Minnesota workers estimate that the current of high-energy electrons producing the X-rays in the Minneapolis experiments described in *Bulletin No. 10* is at least 3×10^6 electrons/cm^2/sec, and probably an order of magnitude greater. It is, therefore, approximately equal to auroral proton fluxes and to the fluxes observed in soft radiation at rocket heights. The X-ray bursts usually appear when a homogeneous auroral arc develops a strong ray structure, or when rays increase in intensity.

X-ray bursts were also observed during the auroral storm of February 10–11. These showed a strong correlation with large magnetic bays (increases or decreases in intensity of magnetic-field components, recorded as bay-like indentations in the graph of intensity variations with time) observed at Fredericksburg Observatory and with cosmic-noise absorption in the ionosphere observed at Boulder, Colorado. X-ray bombardment in the daytime was observed on several other occasions during sudden intensity decreases in cosmic radiation accompanied by increased geomagnetic activity. However, no auroral correlation was possible.

Solar Gamma Rays: During a balloon flight in Cuba, a strong burst of what are believed to be solar gamma rays was observed by the University of Minnesota investigators coincident with a solar flare. The burst lasted 18 seconds and was also exactly coincident with a strong radio-noise burst. The energy of the gamma radiation was estimated at 0.5 mev. The investigators believe it may have arisen from nuclear processes excited during the flare, since it is difficult to account for by more usual mechanisms.

Latitude Effect: The remarkable latitude effect reported in *Bulletin No. 3*, in which changes of cosmic ray intensity could be detected within a latitude change of as little as seven miles at Minneapolis in the fall of 1956, has now vanished owing to the removal of low-energy particles from the cosmic ray spectrum during the solar maximum in 1957–1958. At present, no change with latitude is detectable. A large effect is still detectable at Texas, as the

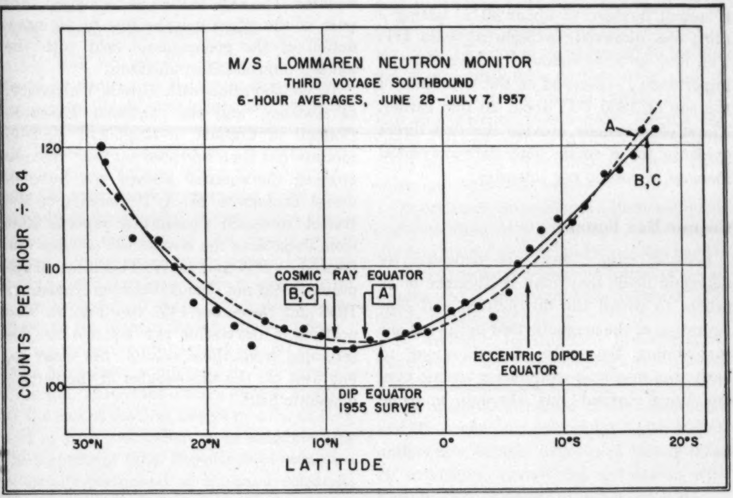

Fig. 6. *Typical Set of Data Used to Locate the Cosmic Ray Equator (line of minimum cosmic ray intensity). A, B, and C are analytical curves of successively higher order fitted to the data by the least-squares method to provide a smooth variation through the experimental points. (Although they represent second- and third-order mathematical terms, respectively, curves B and C are identical.)*

energies still present in the primary spectrum are latitude-sensitive at that location.

Rapid Fluctuations: The cosmic ray monitoring program in general shows many fluctuations of the primary radiation at 100,000 ft which are well correlated with fluctuations observed at sea level by neutron monitors and by ion chambers.

Balloon experiments were conducted by J. J. Corrigan, S. F. Singer, and M. J. Swetnick, of the University of Maryland, to detect rapid fluctuations in the low-energy component of cosmic rays and to detect small solar-flare effects. A high-counting-rate Geiger telescope was flown in an aircraft at altitudes of 25,000 to 45,000 ft at geomagnetic latitude 55°N.

No rapid fluctuations were observed on a flight on August 8, 1957, but at 1349 UT, August 9, while the balloon was flying at 25,000 ft, an increase of about 30% began. It lasted about 2.7 min. At the same altitude, a second increase of about 30%, lasting 2 min, was observed to begin at 1433 UT. The first increase followed a solar flare of importance 1, observed on the west limb of the sun at 1330 UT, about 20 min earlier. These observations provide the first direct evidence for a small, solar-flare-associated increase in cosmic ray intensity.

Cosmic Ray Equator

Because cosmic rays are deflected by magnetic fields they may be thought of as probes to reveal the distribution and configuration of the magnetic field in the regions surrounding the earth. Investigations to locate the magnetic equator for cosmic rays are being carried out through multiple crossings of the equatorial region by ships and aircraft.

Investigation of the location of the magnetic equator for cosmic ray particles, under the supervision of J. A. Simpson, University of Chicago, was begun with the USS *Atka* and by three round-the-world Antarctic expeditions of the USS *Arneb*. The ships carried cosmic ray neutron monitors back and forth across the equator. In addition, twelve equatorial crossings were carried out within a short time interval by high-flying aircraft fitted with neutron detectors.

As a result of these investigations, a 25% variation of maxima with longitude was determined for the first time. Also, results show that the magnetic center of the earth for cosmic ray particles is about 45° west of the magnetic center derived from spherical harmonic analysis of geomagnetic data. The cosmic ray equator was found to lie close to, but west of, the surface magnetic-field dip equator. The shift is such as to suggest that part of the effect may be due to an interaction of the geomagnetic field with the ionized interplanetary medium.

In collaboration with Upsala University, of Sweden, and the National Research Council of Canada, a shipboard neutron monitor has been operated on four voyages crossing the equator aboard the Swedish vessel *Lommaren*. M. A. Pomerantz of the Bartol Research Foundation reports that from these data the cosmic ray equator was located at 8°N and 14°W. This location apparently did not change between November 1956 and December 1957 (see Fig. 6). The position of the cosmic ray equator as determined from these results, lies close to, but west of, the dip equator of the earth's magnetic field.

NATIONAL ACADEMY OF SCIENCES

Number 16 • October 1958

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Oceanography Program: First Twelve Months

The following report is based on material supplied by Gordon G. Lill, Head, Geophysics Branch, Office of Naval Research, Washington, D. C., Roger R. Revelle, Director, Scripps Institution of Oceanography, La Jolla, California, and other participants in the IGY Oceanography Program.

Deep Water Ship Operations

The IGY brought the element of international cooperation to the systematic study of the oceans. Single institutions and countries have lacked sufficient oceanographic vessels for large-scale, coordinated investigations. But in the IGY Deep Water Ship Program, over 20 countries are operating more than 80 ships in coordinated studies of the circulation and currents of the major ocean basins. Cruises vary from several hundred miles to 40,000 miles or more in length, from a few days for off-shore observations to as much as ten months for extended studies.

Five extensive cruises and several shorter ones have been completed in the US-IGY Program. Three long cruises were in progress at the end of the first twelve months of IGY and at least two others were scheduled for the summer of 1958. Because data reduction is usually performed by the same scientists who carry on the cruise work, results are not yet available from all cruises. However, a number of important findings have already been announced.

Vema: The oceanographic vessel *Vema*, of the Lamont Geological Observatory, Columbia University, made her first IGY cruise, from New York to Recife, Brazil, just prior to the beginning of IGY. The *Vema* then left Piermont, New York, on November 8, 1957 on an Atlantic Cruise to Capetown, South Africa, arriving there on April 7, 1958 (see Fig. 1). This was the first half of an extended cruise expected to end in September 1958. The cruise was planned to include the Scotia Sea, east of the lower end of South America, the Indian Ocean, and the Red and Mediterranean Seas. During the South Atlantic portion of the cruise, cooperative operations were conducted with Brazilian and Argentine vessels.

Objectives were to obtain a more complete understanding of the geologic structure of the continental shelves and the ocean basins, to study the large-scale circulation of ocean waters, and to investigate the nature of sediments on the ocean floor.

In addition to standard oceanographic instruments, the *Vema* is using a new nuclear precision magnetometer, new equipment for study of the CO_2 content of the atmosphere and the ocean on a continuing basis, and an underwater camera capable of taking some 70 exposures, permitting correlation with bottom data gathered by other methods.

To study the geologic structure beneath the ocean floor and the continental shelves, seismic refraction measurements are made by two ships working together. The Bra-

Fig. 1. *Tracks of 1958 IGY Oceanographic Cruises, and Locations of IGY Island Observatories*

Table 1. Types and Number of *Vema* Observations

Program	*No. of Observations*
Standard hydrographic stations	43
Oxygen samples	956
Salinity samples	986
Reversing thermometer water temperature determinations	956
Carbon-14 samples	52
Tritium samples	57
Underwater camera stations	40
Sediment cores	72
Seismic refraction profiles	115
Reversed	15
End-on	100
Plankton hauls (horizontal)	70
Vertical biological hauls	75
Bottom biological trawls	38
Bathythermographic observations	1275
Sub-bottom depth recorder track (nautical miles)	900
Precision depth recorder track (nautical miles)	18,000
Magnetometer observations (nautical miles of track)	16,900
Carbon Dioxide measurements	
Nautical miles of continuous observations	18,000
Number of single samples run	150

zilian vessel *Forte de Quimbia* and the Argentine vessel *Sanaviron* cooperated with the *Vema* in the occupation of seismic stations along the continental shelf of South America and in adjacent waters. The geologic structure beneath bays and several estuaries was studied using a sub-bottom depth recorder, a new instrument similar to the echo sounder.

Table 1 provides a count of observations of different types made by the *Vema* on this first portion of the cruise.

Crawford: The research vessel *Crawford*, of the Woods Hole Oceanographic Institution, has added several Atlantic sections to its earlier work, completed in the pre-IGY period (see *Bulletin No. 2*). In addition, it conducted some significant studies in the Caribbean Sea.

The *Crawford's* observations will be compared and correlated with similar data obtained by the Woods Hole research vessel *Atlantis* 30 years ago in the hope that this will shed new light on the circulation of the Atlantic Ocean. Efforts will be made to determine the age of the water in the enclosed Caribbean Basin. Of particular importance is knowledge of the depths of sills—submarine ridges separating partially closed basins from one another, or from the adjacent ocean, and blocking exchange of deep water.

During the *Crawford's* cruise, some basins were found in which the deep water is isolated from both North Atlantic and Caribbean deep waters. Moreover, the characteristics of this isolated water suggest that it is residual from previous ocean circulation patterns that existed under different climatic conditions.

The water samples collected on the cruise, along 10 transverse Atlantic sections, provide for the first time adequate information about the distribution of organic and inorganic phosphorous in the sea. On the basis of this information, the Woods Hole scientists now believe that plankton productivity in the open sea may be twice previous estimates.

Hidalgo: The research vessel *Hidalgo*, of Texas Agricultural and Mechanical College, is now carrying out an IGY oceanographic cruise in the Atlantic, Caribbean, and Gulf of Mexico (Fig. 1). This cruise is intended to tie into Lamont and Woods Hole cruises to help fill gaps in our knowledge of the oceans to the south and southeast of the United States.

Atlantis: The *Atlantis*, of Woods Hole, left late in April of this year for the Indian Ocean, via the Mediterranean and Red Seas. She met the *Vema* of Lamont Geological Observatory in the Indian Ocean, where the two ships conducted seismic operations to study the sub-oceanic crust and made standard oceanographic observations. They then made traverses of the Red Sea, which had never before been studied in this manner. The floor of the Red Sea is thought to consist of a gigantic rift; in the Red Sea itself, deep water of very high salinity has been observed. In July, the ships worked in the Mediterranean Sea, returning to the United States in late summer through the Atlantic.

Brown Bear: In the summer of 1957, the University of Washington research vessel *Brown Bear*, made a cruise in the Northeast Pacific (see *Bulletin No. 9*). A unique feature of the University of Washington program was the conversion of data to punch cards while still aboard ship.

A second IGY cruise of the *Brown Bear* got under way on June 30, 1958. The region under study was the eastern Pacific between about 32° and 50°N, and as far west as about 146°W (Fig. 1). The cruise plan included reoccupation of stations occupied 30 years ago by the *Carnegie*, of the Carnegie Institution of Washington, for comparison of present-day data with that obtained by the *Carnegie*. The ship returned to Seattle, its home port, on August 24.

A special objective of the cruise was to determine the location of the transition zone between the subarctic and central regions of the northeastern Pacific. As on the 1957 cruise, data were transferred to punch cards aboard ship.

Downwind Expedition: The *Horizon* and *Baird*, research vessels of the Scripps Institution of Oceanography, University of California, completed a five-month expedition in the Southeast Pacific—the "Downwind Expedition"—in February 1958. *Bulletin No. 7, January 1958*, describes the aims of the expedition, techniques used, and results of the first few weeks' work. From this information and from data collected on the remainder of the expedition some preliminary conclusions are possible.

There are indications that North Pacific deep water extends to the Tuamotu ridge, a projection of the East Pacific rise. South of the Tuamotu ridge, the deep water is of Antarctic origin.

It was found that in regions of uplift of the earth's crust beneath the oceans, such as the Easter Island Rise (the Albatross Plateau), the heat flow in bottom materials was larger than normal. Near regions of severe downwarping of the crust, in the vicinity of the South American Trench along the western edge of the continent, for example, the values were much lower than expected. These findings support the theory that great convection currents exist within the earth's mantle—the layer directly beneath the crust. These currents are believed to carry hot material upward toward the base of the crust in regions of uplift and cooled material downward toward the core of the earth in regions of downwarp. Such convection currents may actually be the cause of the uplifts (plateaus) and downwarps (trenches).

There was considerable variation of crustal thickness beneath seismic stations occupied on the cruise. A basin just east of the Easter Island Rise had one of the thinnest crusts yet found—2 km, or less than half the normal sub-oceanic crustal thickness. Beneath Nasca Ridge, on the other hand, at an average depth of 1600 fathoms, one of the greatest sub-oceanic crustal thicknesses was discovered—perhaps as much as 15 km.

Preliminary analysis aboard ship of some of the seismic data gathered in the equatorial zone of carbonate bottom sediments confirmed previous observations that this sedimentary layer is about twice the mean oceanic sediment thickness of a few hundred meters. Bottom sediment thicknesses observed during the Southeast Pacific part of the cruise, on the other hand, were no greater than normal thicknesses in the Central and North Pacific. At nearly all stations occupied on the cruise, a "second layer" was found between the unconsolidated sediment and the principal crustal layer. Its thickness is generally about 1 km, although in some places it is several km thick.

Ionium/thorium ratios at various depths in the ocean-bottom sediments indicate that the rate of accumulation of these sediments can be measured in millimeters over thousands of years.

One unusual finding was the discovery of an extensive area in which the sea floor is covered with a loose layer of nodules having rich concentrations of manganese, copper, cobalt, and nickel.

Dolphin Expedition: In the spring of 1958, the research vessels *Horizon*, of Scripps, and *Hugh M. Smith*, of the Pacific Oceanic Fishery Investigations, US Fish and Wildlife Service, completed a two-months' cruise in the Equatorial Pacific (Fig. 1). The cruise, called the "Dolphin Expedition," explored the Cromwell Current which runs counter to the South Equatorial Current some hundreds of feet beneath it.

This eastward-flowing countercurrent, first discovered at 150°W in 1952, has now been traced for about 3500 mi. Although the origin and westward extent of this current are still unknown, the Dolphin Expedition has established that it disappears at the Galapagos Islands. The countercurrent is about 250 mi wide and has a speed of approximately 3.5 mph; this is more than 2 mph faster than the South Equatorial Current, which flows westward above it. Expedition members first located the countercurrent 100 ft beneath the surface. Its core lay about 300 ft below the surface, becoming shallower eastward, and its total thickness was found to be about 700 ft. This countercurrent transports a volume of water approximately equal to that moved by the Gulf Stream where it emerges from the Straits of Florida. It is thought that this great countercurrent may be an important refertilization mechanism, contributing to the unusual abundance of marine life in this part of the equatorial Pacific.

Beneath this swift, eastward-flowing countercurrent still another current—a weak one, flowing westward—was found. Thus, in the upper few thousand feet of this part of the Pacific there are three ribbon-like currents, lying one on top of another and flowing in opposite directions.

Antarctic: The logistic support afforded the IGY Antarctic Program by US Navy Task Force 43 presented an opportunity for limited oceanographic studies in Antarctic waters by scientists aboard Navy and Coast Guard icebreakers.

Detailed temperature profiles of the Antarctic Convergence have been largely lacking in the past. (The Antarctic Convergence is the zone in which the cold waters of the Antarctic Current sink beneath, and to some extent mix with, the warmer waters of the West Wind Drift.) Hence, special emphasis was placed on such work during the cruises and new information was gathered on the geographic location of the Convergence. In the Indian Ocean sector, the Antarctic Convergence was identified in the vicinity of 55°S. Crossings in the Atlantic sector located it near 56°S, 55°W and near 52°S, 38°W. In the vicinity of the International Date Line, in the Pacific sector, the Convergence was found near 62°S.

Because icebreakers are now able to penetrate deeply into ice-locked Antarctic regions, they have obtained oceanographic data in places hitherto inaccessible and at times during which scientific field study was formerly impossible. Stations in the Weddell Sea in 1956–57 indicate that there is very little change of density with depth. Across the head of the Sea, on the continental shelf, the water temperature was uniformly slightly above −2.0°C from a depth of 100 m to 600 m. Air temperatures ranged from −2.8°C to −6.2°C. Therefore, although it was less than a month past Antarctic midsummer (January 11–20), the sea was losing heat to the atmosphere, and winter cooling had already begun.

Weddell Sea studies verify the theory that Antarctic bottom water is formed by a mixing of the cold, heavy surface water—originating on the continental shelf by winter cooling and freezing—with the warmer circumpolar subsurface water.

In the Ross Sea, one of the highest densities ever met in the ocean—28.14 (gm/liter above 1 kg)—was obtained at a depth of 515 m, only 5 m above the bottom. This suggests the existence at that location of a basin in which very dense water is trapped.

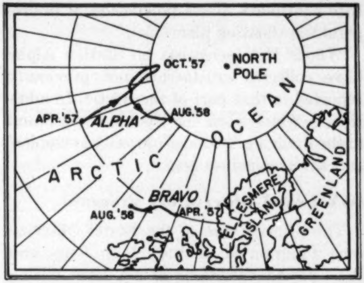

Fig. 2. *Tracks of IGY Drifting Stations Alpha and Bravo Since Their Occupation.*

Oceanographic stations were reoccupied periodically over several months' time near IGY Little America Station and near Hut Point, in McMurdo Sound. At both places there was a rapid summer decrease in salinity, apparently reflecting melting of the pack and shelf ice; warming of the sea was confined to the upper layers. During the winter, cold brines sinking from beneath the thickening pack ice raise the salinity of the waters over the continental shelf.

Marked differences between the regimes of the waters near Hut Point and near Little America Station are probably caused mainly by the difference in the thickness of the ice bodies near these waters. In the vicinity of Hut Point the ice barrier is relatively thin compared to the 250-m thickness of the Ross Ice Shelf near Little America.

Drifting Stations: In the Arctic Ocean, IGY oceanographers pursue their investigations from stations on the drifting pack ice (Fig. 2). This and other Arctic Basin work and some of the results obtained were reported in *Bulletins Nos. 1, 2, 4, 6, 8, 9,* and *12.*

Further results are continually being made available: Hydrographic observations made at Drifting Station Alpha show a uniform temperature of −1.7°C (+29.0°F) from the surface to a depth of 900 ft. Micrometeorological observations indicate that this value has remained constant for a considerable length of time. Regular plankton hauls indicate continued sparse population of phytoplankton (floating plant life).

Woods Hole scientists on Station Alpha have collected crustaceans not previously reported in that part of the Arctic. In addition, a water-worn coral pebble was found in the dredging. (Coral grows only in tropical and sub-tropical waters.)

IGY Island Observatory Program

The primary aim of the Island Observatory Program is to study both long- and short-period variations of sea level during the IGY. A number of other phases of oceanographic work are included. Sea-atmosphere relationships receive particular emphasis (see *Bulletins 2*, *4*, *6*, and *9*).

In the Pacific, the Island Observatory Program is directed by the Scripps Institution of Oceanography. The Atlantic program is directed by the Lamont Geological Observatory. Many other US agencies and individuals are contributing directly to the work, and Iceland, Chile, Ecuador, France, Great Britain, Portugal, and Mexico are cooperating in joint projects. United States agencies assisting in the program are the Coast and Geodetic Survey, Weather Bureau, Navy, and Fish and Wildlife Service.

Analysis of data gathered at Pacific observatories (Fig. 1) has yielded the following results, among others:

Long-Period Waves and Local Weather: Qualitative study of the daily background at the long-period wave stations indicates that local weather is directly related to the amplitude of sea swell and surfbeat. Short trains of long-period waves (10–90 min) occur daily. Marcus Island records show several occasions during which local squalls passing over or near the island produced sea-level changes that quantitatively corresponded to variations in barometric pressure.

Hurricane Waves: Four hurricanes occurred during the period November 1957–April 1958; the waves from each were recorded at one or more stations. The first wave arrivals consisted of long undulations of sea level with periods of 10–20 min. These were followed by great intensification of the surfbeat and the sea swell. The entire process from normal to peak activity occurred within three hours at stations within 200 mi of the disturbance. At distant stations, as much as 24 hours elapsed between the long-period forerunners and the swell.

Tsunamis: A statistical study of inundation heights from tsunamis (so-called tidal waves resulting from submarine earthquakes, landslides, or volcanic action) around the Hawaiian Islands is in progress. The study indicates that the local height of on-shore waves on a nearly circular island can be adequately represented by a simple empirical equation. Using this equation, an apparent inverse relationship was found between the individual wave heights and the offshore slope. In all cases, the distance from crest to crest at the beginning of the slope was of the order of magnitude of the island diameter.

Hemispheric Water Exchange: Tide-gauge data from both oceans show a change in mean sea level from summer to winter. Most of this appears to be related to expansion and contraction of water with seasonal temperature changes, but it may also be due to movement of water between northern and southern hemispheres.

Carbon-Dioxide and Radiochemistry Studies

Carbon Dioxide: A coordinated effort is being made by scientists at Scripps, Woods Hole, Lamont, the University of Washington, and Texas A & M to gain an understanding of the CO_2 content of the atmosphere and oceans.

Man, in his burning of fossil fuels and denudation of the land's surface, may be performing a gigantic geophysical experiment in which the CO_2 cycle is being influenced. It is thought we may be increasing the CO_2 input into the atmosphere by 70% in 40 years, although it is not certain how much of this may be absorbed by the oceans. A substantial increase in CO_2 content in the

Table 2. Radiochemical Analyses

Woods Hole	*Scripps*	*Lamont*	*Texas A & M*	*U of Wash.*
H^3, C^{14}, Sr^{90}, Sb^{125}, Cs^{137}, Ce^{144}, Pm^{147}	H^3, C^{14}, S^{89}, Sr^{90}	H^3, C^{14}	C^{14}	C^{14}

air would trap more of the earth's radiated heat and cause a warming of temperatures.

Data collected during the IGY will be needed for comparison with measurements made 15 to 25 years from now to determine whether the CO_2 content is changing. It is now possible, owing to availability of a gas analyzer capable of a precision of $\frac{1}{10}$ part per million (ppm), to achieve the accuracy required for such determinations.

Atmospheric CO_2 measurements made on the Downwind Expedition indicated a very slight but distinct latitudinal variation. Its range was about 3–4 ppm. In general, it was found that CO_2 tension in the sea water, that is, the part of the total pressure caused by CO_2, exceeded that in the atmosphere. An observation near the Chilean coast showed extraordinarily high CO_2 tension, apparently the result of upwelling of the deep water.

Results of IGY investigations thus far indicate a remarkable constancy of CO_2 content in the atmosphere. At IGY Little America Station, Antarctica, the variation during a period of more than one year was only 0.3%. Continuous measurements over a period of two months at Mauna Loa Observatory, Hawaii, showed a variation of 1.0%. Measurements made continuously aboard research vessels in the Pacific between the Bering Sea and Valparaiso, Chile, in 1957, show a variation of 2.0%. The mean values for all of these locations lie very close together. Air samples collected in the Gulf of Alaska and at Cape Hatteras in April 1958 also yielded concentrations of CO_2 whose mean values were very close to those obtained at the above locations.

Radiochemistry: Those institutions carrying out the CO_2 program are also performing radiochemical analyses of sea water. Such analyses are used to determine the circulation of the oceans and the age of sea water at various levels. Table 2 lists the kinds of radiochemical analyses being made at the participating institutions.

Future Plans

The international cooperation which is such an integral part of the IGY has had a profound impact on oceanographers. As a result, the International Council of Scientific Unions (ICSU) has organized a Special Committee on Oceanographic Research (SCOR) to foster similar cooperative programs in the future. Several meetings of SCOR have already been held, and plans have been made for a long program of oceanographic research in the Indian Ocean, about which little is now known. In the course of this work, encouragement and training will be given to scientific talent in bordering countries. Similar work will eventually be performed elsewhere.

The National Academy of Sciences has also recognized the need for long-range planning in oceanography, and has organized a new Committee on Oceanography, under the chairmanship of Harrison Brown, California Institute of Technology. The Academy's Committee contains several panels to study specific questions, such as design of oceanographic research vessels, new devices to explore the oceans, and marine resources. The Academy's Committee will carry out liaison with SCOR.

The planning of both SCOR and the Committee on Oceanography carries far beyond the specialized IGY program in oceanography. Included are marine biological studies, with emphasis on fisheries and food production in the sea, and concerted attacks on hitherto little studied regions.

Ionospheric Electron-Density—Height Profiles

Material for this report was furnished by E. R. Schmerling of Pennsylvania State University.

For many years a large number of stations, widely dispersed over the world, have been sounding the ionosphere—the electrically charged region of the atmosphere which reflects radio waves—and recording the results. The most widely used method is to send pulsed radio signals vertically upward. The time-delay of the echo of each pulse from the ionosphere is shown on an oscilloscope. A photographic record of the oscilloscope trace relates the heights of the echoes to the different radio frequencies used. Such a record is called an ionogram.

Customarily, only several easily-obtained descriptive characteristics of the ionosphere are obtained from the ionograms. Use of these characteristics in the prediction of the most suitable radio frequencies for communication purposes has been outstandingly successful. The values obtained from ionograms are regularly published by national organizations—in the United States, for example, by the Central Radio Propagation Laboratory (CRPL) of the National Bureau of Standards.

Measurement of Ionograms

Ionograms show the virtual heights of reflection of radio pulses of different frequencies. The virtual height, by definition, is the time between the transmission of a pulse and its return, multiplied by half the velocity of light in free space. Since radio pulses do not travel in the ionosphere with this velocity, the virtual height is generally very different from the true height of reflection.

Reflection is due to the presence of free electrons in the ionosphere; at the reflection point, the electron density is related to the radio frequency of the reflected pulse. If the true height of reflection can be found from the ionogram, the ionogram will provide a profile of electron density at different heights. Such profiles give a very detailed picture of the ionosphere. They are of great value to the radio physicist, for with more precise knowledge of how the ionosphere behaves, he can better formulate and test theories of its origin and character.

The processes which affect the electron densities in the ionosphere can be classified as electron-production (mainly resulting from solar radiation), electron-loss (recombination and molecular attachment) and electron-drift (owing to winds of tidal and electrodynamic origin). These processes are imperfectly understood.

Most previous work has been based on the critical frequencies (the maximum frequency reflected by a given ionospheric layer) and on the minimum virtual heights of the various ionospheric strata, or layers. These are easily measured from the ionograms, but give very incomplete information. The critical frequencies give electron densities at the peak densities of the layers but do not specify their heights. The minimum virtual heights are of uncertain significance as they are determined as much by the underlying ionization as by the true lower boundaries of the layers. Since the production, loss, and drift rates are extremely dependent on height, and since considerable movement of the layers takes place, the height specification is of great importance.

Electron-Density Profiles

The reduction of ionograms to electron-density profiles is mathematically a complicated problem. It is like deducing the contour of a hill from observations of the time needed for a ball, after one push, to roll up one side and down again. As far back as 1930, the physicist de Groot showed that the two problems are formally identical if the effect of the earth's magnetic field is neglected. If the effect of the earth's mag-

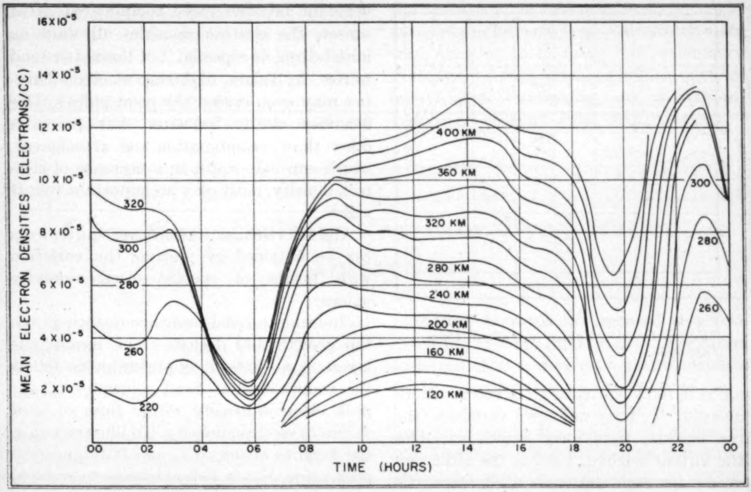

Fig. 3. *Daily Mean Electron Densities at Talara, Peru, During July 1957*

netic field is included, the problem is even more complicated.

Important work has been done by J. M. Kelso, who, while at Pennsylvania State University, devised a rapid but approximate method of solution. Several more precise methods of solution are now available. A matrix method devised by the British scientist K. G. Budden (1955) includes the effect of the earth's magnetic field and determines the profile without making assumptions concerning the profile shape; it is assumed, however, that the electron concentration does not decrease with altitude. (This condition does not usually hold everywhere in the ionosphere, but the assumption can be assessed in using the method, and is generally found to be of minor importance.)

IGY Program

During the IGY, data-reduction programs have been set up in England and the United States. The two programs give reasonable global coverage and lay the foundations for a world-wide survey. For the US program, under the supervision of E. R. Schmerling ionograms are being selected from the following four stations: Washington, D. C.; Talara, Peru; Canal Zone; and Huancayo, Peru. Records are reduced at the Pennsylvania State University for every hour of the three Regular World Days and the 10 magnetically quietest days of each month. This is actually a very small selection from the available data. However, the program is a minimum one aimed at determining electron density behavior so that ionospheric theories may be formulated and tested. Recently, another program of reduction of ionograms for true heights was initiated at CRPL, in Boulder, Colorado. It is directed toward providing electron-density profiles of the ionosphere at locations where radio signals from satellites are observed after propagation through the ionosphere.

"Forty-by-forty matrices" have been developed at Pennsylvania State University for the reduction process. These matrices are arrays of the numerical coefficients con-

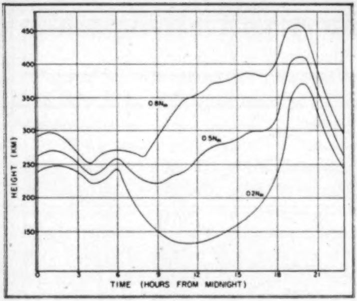

Fig. 4. *Variation With Height of Specific Electron-Density Values at Talara, Peru, July 1957.*

tained in forty equations to be solved simultaneously for forty unknown variables (the true heights) from forty known variables (the virtual heights). Used in the reduction process for each station is a characteristic matrix that depends on the magnetic field at that location. Development of the matrices is being carried out on the University's digital computer, PENNSTAC. Measurement of the virtual height of the ionograms at specific frequencies by scaling is performed manually in 10–15 minutes per record; the computer then performs the reduction in approximately one minute, and prints out true-height values for specified values of electron density.

Preliminary Results

For survey purposes, it is useful to average out some of the day-to-day fluctuations. This can be done conveniently by reading off the electron densities from the profiles at 20-km height intervals, and averaging these over all of the days in each month. The mean curve for Talara produced in this way for July 1957 is illustrated in Figure 3. These curves have several features in common, but they also show some striking differences. Near sunrise, the electron densities increase rather rapidly at all heights, as would be expected. At night, however, the behavior becomes more complicated. Near sunset, the electron densities all show an initial drop, as expected, but thereafter tend to rise. At Talara, nighttime electron densities may even exceed the noon values. This behavior clearly indicates that processes other than recombination and attachment, which can only result in a decrease of electron density, must play an important role at night.

A good visualization of layer movements can be obtained by plotting the variation with height of specific electron-density values.

(In order to avoid confusion resulting from the growth and decay of the ionospheric layers as a whole, it is preferable to follow the movements of fixed multiples of the peak electron density rather than of fixed values of electron density. To illustrate this, the heights of 0.8, 0.5, and 0.2 times the peak value, N_m, at Talara have been graphed with respect to time in Figure 4).

The mean curves that result characterize the height movements, and their spacing provides a measure of the thickness of the ionospheric layer. It is seen that the bulk of the ionosphere is lower by day than at night. An empirical explanation of the nighttime increase of electron density is also immediately apparent, since the thickness decreases markedly. The nighttime increase is thus due to compression of the ionosphere rather than to a nocturnal source of ionization with a peculiar geographical distribution.

It is pertinent to inquire into the differences of behavior at the four stations. These have been chosen quite close to the 75°W meridian, but with widely different geographic and geomagnetic latitudes. The differences of behavior are, in fact, closely linked with the local magnetic dip, as shown by Sir Edward Appleton of the United Kingdom in 1950 and 1954. A natural explanation is found in terms of electrodynamic movements, since tidal winds acting on charged particles produce electron movements that are profoundly influenced by the local inclination of the magnetic field. This was pointed out by D. F. Martyn of Australia in 1947. While the details are still obscure, the general effects are fairly clear.

No more than a start has been made on the provision of electron-density—height data on a sufficiently large scale. Much more work remains to be done, but preliminary evaluation of data already available is yielding valuable information and guiding investigators to some of the right questions.

Deep Core Drilling Program: Byrd Station, Antarctica

The following report is based on material supplied by J. A. Bender, Chief, Snow and Ice Branch, SIPRE. The drilling program was carried out by glaciologists E. W. Marshall, Project Leader, R. W. Patenaude, and A. C. Gow; Chief Driller was J. B. Tedrow.

During the summers of 1956 and 1957, the US Army Snow, Ice and Permafrost Research Establishment (SIPRE) conducted drilling operations at its experimental station on the Greenland Ice Cap. (See *Bulletin No. 7, January 1958*). Although the Greenland drillings produced valuable glaciological and climatological data, their primary purpose was to develop techniques for drilling and core removal in ice.

These techniques were used at IGY Byrd Station in the Antarctic during the 1957–58 summer season to obtain 4-inch cores to a depth of 1013 ft. While the hole was not as deep as that drilled in Greenland in 1956, the core samples recovered are formed of snow of much greater age. (The ice at the 1000-ft level at Byrd Station is formed from snow which fell about 1400 years ago. The age of the deepest core from Greenland is about 950 years. The difference follows from the relatively light precipitation in the Antarctic.)

Drilling Methods

The core drilling at IGY Byrd Station was accomplished with equipment and techniques similar to those employed in coring rock. Major exceptions were the bits, core catchers, drilling fluid, and a specialized core-feed device developed to compensate for the fragility of the ice to be cored.

Previous experience had shown that very low bit pressures are required for drilling in ice. Therefore, all of the drilling and coring was done with the drill string in tension. But the rate of feed became irregular as the weight of the drill string increased with depth. To correct this, a hydraulic core-feed device capable of very fine adjustment was developed, making possible a perfectly constant rate of feed.

In order to prevent the ice from shattering while coring, it was necessary to control the rotation speed of the bit and the rate of penetration within narrow margins and to hold vibration of the core barrel and bit to a minimum. The success of the measures used is shown by the fact that 98% of the core was recovered in usable condition.

Cold compressed air under a pressure of 60 lbs/in^2 was used as the drilling fluid. The temperature of the compressed air varied with the temperature of the outside air but was always kept well below freezing. In the permeable upper layers of the snow, the air tended to dissipate into the snow instead of circulating; as a result, the cuttings adhered to the hole wall or fell back down the hole. This difficulty was solved by casing the drill hole to a depth of 115 ft, where the snow was sufficiently impermeable to maintain air circulation.

Table 3. Mean Deep-Core Densities

Depth (In meters from surface)	*Density (gm/cm^3, ± 0.005 cm)*

Analysis of Cores

Close inspection of the early cores revealed a detailed stratigraphic sequence. Alternating layers of coarse- and fine-grained snow were associated with thin ice bands (4 mm) at regular intervals in the cores. Thick bands of ice, indicative of pronounced thaws such as would occur in summer on a temperate zone glacier, were not recognized. However, it is hoped that a detailed density analysis of successive layers in the stratigraphic sequence will permit investigators to distinguish between summer and winter snows and to determine the extent of yearly accumulation.

Work at Byrd Station: The ice cores were placed in a trough and viewed from above with the aid of a light source placed under the trough. The exact positions of ice layers were determined by use of a measuring tape laid along one edge of the trough. The nature of the layers (whether coarse, fine, or icy) was also recorded. Successive sections of the core were then photographed. This combined stratigraphic-photographic procedure was begun on cores taken from the 60.3-ft (18.36-m) level and continued on cores down to the 319.5-ft (97.38-m) level. The photographs were mounted in order on cardboard sheets to give a running stratigraphic column through this interval. Distinctive layering could be observed in cores from depths down to 400 ft. Below this, the cores were homogeneous and visible stratification disappeared, with the exception of the thin ice bands; these persisted to the bottom of the drill hole.

Determinations of the density of individual layers were started using cores from the 60.3-ft level (18.36-m) and completed to 154.4 ft (47.06-m). These determinations were made in the time available at IGY Byrd Station. In all, densities were calculated for 700 core segments ranging in length from 15 cm to slightly less than 1 cm.

Mean densities of 1-m increments have also been calculated; these are presented in Table 3. Densities were also determined for spot samples selected at depths of 123 m, 150 m, 173 m, 200 m, and 222 m (Table 4). The density of the sample from the 222-m depth approaches the maximum value for ice, 0.917. Thin sections were made from the same samples and examined under the microscope for grain-size differences. There was insufficient time to carry out detailed fabric studies of the thin sections while at Byrd Station.

The core from a 3-in, hand-augered hole sunk to a depth of 71 ft (21.6 m) was similarly treated. Densities from 176 segments were determined for the first 30 ft and mean densities for 1-m increments were calculated (see Table 5).

Work at SIPRE: At the outset of drilling

Table 5. Mean Densities of Hand-Augered Cores

Depth (In meters from surface)	*Density (gm/cm³, ± 0 .005 cm)*
2.32–3.00	0.449
3.00–4.00	0.405
4.00–5.00	0.421
5.00–6.00	0.432
6.00–7.00	0.487
7.00–8.00	0.515
8.00–9.00	0.526
9.00–9.37	0.536

at IGY Byrd Station it was intended to split the 4-in cores lengthwise. One half was to be returned to SIPRE, at Wilmette, Illinois, for further research and the other half was to be retained at Byrd Station for use in further studies in the Antarctic. However, because of the large amount of detailed stratigraphy in cores from depths down to 400 ft, it was decided to keep cores from this section of the drill hole in their original state. Splitting of cores from the lower 600 ft was begun, but because of failure of the band saw, cores from the lowest 160 ft remained uncut. Both of the uncut core sections, half the longitudinally split cores, cores from the 71-ft auger hole, and cores from two shallower holes at IGY Byrd Station were transported from the Antarctic aboard the USS *Glacier*. The cores were maintained at 0°F throughout the trip to Boston, where they were unloaded and transported by refrigerated truck to the SIPRE laboratories at Wilmette.

Further research at Wilmette will include the completion of the density profile, grain-size and petrofabric studies, analysis of enclosed foreign particles, measurement of gas-bubble pressure, chemical analysis of entrapped gas, and measurement of tritium and other radioactive substances. Measurement of the ratios of oxygen isotopes 16 and 18 will be carried out at the California Intitute of Technology.

Note: Temperatures continue to decrease with depth.

Temperature Measurements

Temperature measurements were made in the deep drill hole to a depth of 1000 ft (Table 6) using a 100-ohm thermohm and a Wheatstone bridge temperature indicator.

Thermal conditions in the hole were disturbed by the drilling and by the cold compressed air used as the drilling medium. Therefore, temperature measurements were not begun until three days after completion of the drilling. This allowed the hole to return to thermal equilibrium.

The thermohm was read at 50-ft intervals. It was given a minimum of two hours at each level to come to equilibrium. Instrument errors, reading errors, and the disturbed thermal conditions from the effects of drilling permit an accuracy of ±0.10°C.

Because steel casing was set to a depth of 115 ft, temperatures taken within this upper zone may be subject to errors greater than ±0.10°C.

Progress of the Moonwatch Program

Material for this report was furnished by Leon Campbell, Jr., and Armand Spitz of the Smithsonian Astrophysical Observatory.

Plans for optical tracking of IGY artificial satellites, under the direction of the Smithsonian Astrophysical Observatory, anticipated two phases. Immediately after a launching, the Moonwatch teams of the volunteer visual observation program, using low-power, wide-field telescopes, would search for the satellite. Once the satellite had been located, or "acquired," and its orbit computed, optical tracking would be carried on by the large tracking cameras (see "Optical Tracking of Earth Satellites," *Bulletin No. 12*). However, when the USSR satellites were launched, Moonwatch teams necessarily carried on the visual tracking program until the full complement of tracking cameras could be put into operation.

A measure of the value of Moonwatch teams in the satellite visual observing program is the number of scientifically useful observations produced. Not only have Moonwatch teams provided a great number of observations but the observations cover all the satellites launched to date. With these data, together with the radio tracking data provided by the Naval Research Laboratory, it has been possible for the Smithsonian Astrophysical Observatory to compute preliminary ephemerides that have been used to position the satellite tracking cameras at the IGY precision tracking stations. Furthermore, Moonwatch observations provided almost daily have been utilized in the constant refining of these ephemerides.

Results

There are approximately 230 Moonwatch stations in various parts of the world. Eighty per cent of these stations have contributed observational data. Many of the stations that have not made observations are among those recently organized.

Through May 9, 1958, observations of scientific value have been reported by 181 teams. In these observations, the positional data were accurate to one degree of arc, the time of observation accurate to one second, and the objects under observation were identifiable as satellites or as orbiting parts of the launching vehicles. The stations made either one observation or a group of observations during a single satellite crossing on 1599 occasions.

The following table shows the total observing occasions, or sessions, credited to teams in the indicated areas of the world:

Area	*1957α*	*1957β*	*1958α*	*1958β*	*1958γ*	*Total*
U.S.	278	523	60	8	18	887
Japan	134	348	6	4	—	492
Africa	23	52	41	2	8	126
Australia	31	36	3	2	—	72
Elsewhere	3	18	1	—	—	22
	469	977	111	16	26	1599

At these observing sessions, the following numbers of separate observations were made: teams in the United States, 2013; Japan, 879; Africa, 256; Asia, 21; Australia, 259; South America, 11; Central America, 4; total 3443.

Throughout the period of visual tracking, Moonwatch observational reports have usually furnished data in a sufficiently constant flow to allow for continual refining of preliminary ephemerides of the several objects in orbit. The world-wide distribution of Moonwatch stations has made this possible; as the visibility areas have shifted around the world, there have generally been teams so located as to be able to continue to observe the satellites.

During the early months of the program, reports from United States teams were received by telephone at the Smithsonian Observatory within a few minutes of the actual observations. Recently, telephone reporting has been discontinued in favor of telegraph. The results, with respect to accuracy and speed of transmissions, compare most favorably. Moreover, telegraphic reporting has allowed conservation of the limited manpower at Moonwatch headquarters. Reports from stations outside continental United States have been transmitted, from the beginning of satellite observing, over commercial cable and over IGY and other communication systems. These facilities, too, have proved satisfactory.

Several days before the demise of 1957β, all Moonwatch teams were called upon to set up groups of 4 or 5 observers each to watch throughout the darkness hours of April 12, 13, and 14, 1958, for its fall. Observations of the satellite were made by the three teams toward the very end of the satellite's last revolution. These reports were as follows: Millbrook, N. Y., on April $14^d01^h45^m35^s$; Bryn Athyn, Pa., $01^h45^m46^s$, and New Haven, Conn., $01^h45^m47^s$, (UT). Within a few minutes of these observations, approximately 15 sightings were made of the dying satellite by ships at sea in the Caribbean, and by thousands of persons on islands in the area. Exactly where the satellite and its fragments fell is not determined, but it was last observed over the sea off the coast of the Guianas.

Future of Program

Continued interest in visual observation of satellites is gratifying because of the great deal of observing that undoubtedly lies ahead. Satellite radios may fail before preliminary ephemerides are determined, and observations will need to be made of the dying moments of satellites. Also, each launching may produce not only a radio-signalling satellite, but one or more orbiting components without radios. To date, there have actually been more objects in orbit without radio transmitters than with them.

Gravity Formulas Utilizing Correlation with Elevation

W. M. KAULA

Abstract—Solutions for the first two terms of the standard gravity formula $\gamma_e(1 + \beta \sin^2 \phi)$ were made, all based on the assumption that the gravity anomalies in areas without observations will average the same as observed values of the same elevation. The solution by the method considered theoretically best yields

$$\gamma = (978040.4 \pm 1.3)[1 + (0.0053014 \pm 0.0000030) \sin^2 \phi - 0.0000059 \sin^2 2\phi],$$

and

$$f = 1/298.15 \pm 0.26$$

The coefficients of the fourth and sixth degree zonal harmonics were also computed and used to estimate how much a flattening found from satellite motion would differ. For example, it is estimated that an orbit approximating that of 1958β would give $f = 1/298.00$.

At the Army Map Service, a statistical and harmonic analysis of gravity is being made to take into better account the correlation of the anomalies (1) with topography, and (2) with each other (auto-correlation). The full solution in the form of spherical harmonics will not be completed for some months; however, in view of the interest generated by the flattenings obtained from satellite orbits, a partial solution has been made for a standard gravity formula, utilizing the correlation with topography but neglecting autocorrelation.

In a conventional least-squares solution for a standard gravity formula, a best fit is made to the gravity observations available, combined in some manner, such as 1° × 1° square mean anomalies. In making such a solution, it is implicitly assumed that the gravity anomalies in areas without observations average the same as in areas with observations. Now it is well-known that (1) gravity anomalies have a positive correlation with elevation; (2) the proportionate distribution of elevations of gravity observations differs radically from that of the Earth as a whole, there being an excess of observations on the land as compared with the oceans. These facts are numerically demonstrated by Table 1, which is based on the mean anomalies of 7950 1° × 1° squares.

Table 1 thus indicates that the common assumption, "Gravity anomalies in the unsurveyed areas average zero," is equivalent to the assumption, "Gravity anomalies in the unsurveyed areas average 5.78 mgal higher than in surveyed areas of the same elevation," which sounds less reasonable. The purpose of this paper is to solve for a standard gravity formula with the assumption, "Gravity anomalies in the unsurveyed areas average the same as observed anomalies of the same elevation." 'Unsurveyed area' is defined throughout as any area outside the 1° × 1° squares with observations.

The basic gravity material used is the compilation of 1° × 1° square mean anomalies made by Heiskanen and his assistants at Ohio State University. Only values based on observations within the 1° × 1° square were used; extrapolated or interpolated values were disregarded. In addition, values for 1040 more 1° × 1° squares were obtained from data compiled at the U. S. Navy Hydrographic Office, 130 1° × 1° square means were improved by additional values, and 160 1° × 1° square means at sea were corrected by reduction of the anomaly to the mean elevation of the square. This correction was made not only for squares of more than one observation in the manner described by *Uotila* [1957], but also the average gradient we obtained for 1° × 1° squares at sea, +0.056 mgal/m, was applied to single observations on small islands, etc., to obtain more representative values. Of the additional data, the great majority were observations on the oceans by Worzel and his associates of the Lamont Geological Observatory, and by members of the U. S. Navy Hydrographic Office under supervision of A. L. McCahan.

Mean anomalies, using Δ*g*'s in 4th column: unobserved areas, −5.78; observed areas, +1.45.

---

[a] Italicized values are 0.62 *depth*; height (and depth) values are rounded off to the *nearest* thousand feet.

In latitudes above 50° the 1° × 1° squares were taken to be of more than 1° extent in longitude, in order to maintain approximately equal area: 2° wide from Lat. 50° to 70°; 5° wide, 70° to 80°; 10° to 120° wide, 80° to 90°.

The mean elevations for 1° × 1° squares with observations were obtained from a compilation made in 1952 by the Cincinnati Field Office of the Army Map Service, under supervision of R. F. Van Hart. These elevations were estimated from aeronautical and hydrographic charts averaging 1:1,000,000 in scale. The precision is the nearest 1000 ft; the accuracy is as good as the available maps, except for a few over-estimates in mountainous areas. Since the compilation was originally made for use in isostatic reductions, depths below sea level were multiplied by $(2.67 - 1.03)/2.67 = 0.62$; we have retained these figures in the tables, in order to avoid either a second round-off or non-significant digits.

All solutions were made in terms of nine 10° zones of latitude, the north and the south combined. The portion of each 10° zone falling in each elevation interval was estimated from the 1:10,000,000 Monaco bathymetric charts except for Antarctica, for which the 1:7,000,000 National Geographic Society map was used. For latitudes above 70°, elevations above sea level were assumed supported on the average 20 pct by rock and 80 pct by ice, thus making the mass excess equivalent to $(0.20 + 0.80 \times 1.00/2.67) = 0.50$ times the mass excess for the same elevation on solid rock. A breakdown by elevation also was made at the 1° × 1° squares in each zone, and the mean anomaly Δg_{zh} was computed for each. Table 2 shows the results in terms of Δg_{zh}; r_{zh}, the per cent of the zone represented by Δg_{zh}; s_{zh}, the per cent of the zone of the same elevation without observations; and a_z, the per cent of the total Earth's surface covered by the zone.

The most recent gravity formula computed is that of Heiskanen and Uotila [*Heiskanen*, 1957]

$$\gamma = 978049.6\,(1 + 0.0052934 \sin^2 \phi - 0.0000059 \sin^2 2\phi)$$

$$f = 1/297.4$$

This formula is based on 6679 1° × 1° square mean anomalies; values greater than 75 mgal in absolute value were rejected. In the computations throughout this paper, no values were rejected. Since, as mentioned, we also have considerable additional data for a total of 7950 squares, a conventional least-squares solution was made to serve as a standard of comparison for subsequent changes in method. The mean anomaly for each zone was computed from Table 2 as

$$\Delta g_z = \frac{\sum r_{zh} \Delta g_{zh}}{r_z} \tag{1}$$

These mean anomalies Δg_z are listed in Table 3, together with those of subsequent solutions. Nine observation equations were written

$$v_z = \Delta g_z - (\Delta \gamma_e + \Delta \alpha \sin^2 \phi_z) \tag{2}$$

where $\Delta \gamma_e$ is the correction to the γ_e of the International formula; $\Delta \alpha$, the correction to $\gamma_e \beta$; and $\sin^2 \phi_z$, the mean value of $\sin^2 \phi$ for the zone. Each of these observation equations had a weight of $a_z r_z$. The result is: $\Delta \gamma_e = -1.12$ mgal, or $\gamma_e = 978047.9$ mgal, and $\Delta \alpha = +8.43$ mgal, or $f = 1/297.76$.

Using our rule that gravity anomalies in the unsurveyed areas average the same as observed anomalies of the same elevation, the estimated mean anomaly for each zone will be

$$\Delta g_z = \sum r_{zh} \Delta g_{zh} + \sum s_{zh} \Delta g_h \tag{3}$$

where Δg_h is the mean value for elevation h given in Table 1. The weight of each observation equation now becomes a_z. The Δg_z are again listed in Table 3. The result is: $\Delta \gamma_e = -7.88$ mgal, or

80–90	+11.21	+7.53	+9.59	+45.1
Solution flattening	1/297.76	1/297.90	1/298.15	1/302.6
Solution $\Delta\gamma_e$	−1.12	−7.88	−8.56	−20.8

$\gamma_e = 978041.1$ mgal, and $\Delta\alpha = +9.99$ mgal, or $f = 1/297.90$.

However, the anomalies used in computing the Δg_s are with reference to the International formula flattening of 1/297; if a standard formula of different flattening had been used, the estimated anomalies for the unknown areas would change, and a different solution would be obtained. Let the anomaly with respect to a standard formula differing from the International be

$$\Delta g = g_0 - [\gamma_e + \alpha_j \sin^2 \phi] \tag{4}$$

then with respect to the International formula it will be

$$\begin{aligned} \Delta g_i &= g_0 - [\gamma_e - \Delta\gamma_e + (\alpha_j - \Delta\alpha_j) \sin^2 \phi] \\ &= \Delta g + \Delta\gamma_e + \Delta\alpha_j \sin^2 \phi \end{aligned} \tag{5}$$

The estimate obtained from a sample of n anomalies with respect to the International formula then will be

$$\begin{aligned} \text{Est. } \widehat{\Delta g}_h &= \frac{1}{n} \sum \{\Delta g + \Delta\gamma_e + \Delta\alpha_j \sin^2 \phi\} \\ &= \Delta g_h + \Delta\alpha_j \overline{\sin^2 \phi^h} + \Delta\gamma_e \end{aligned} \tag{6}$$

where $\overline{\sin^2 \phi^h}$ is the mean $\sin^2 \phi$ for the sample. The anomalies (6) are what we get from our data; they are the values in Table 1. If the estimates are being made with reference to a different flattening from 1/297, we want the anomalies (5). Hence in any observation equation using an estimated zone mean anomaly based on data from other latitudes, there should be added a correction equal to (5) minus (6), that is

$$\Delta\alpha_j(\sin^2 \phi_s - \overline{\sin^2 \phi^h}) \tag{7}$$

The $\overline{\sin^2 \phi^h}$ values are shown in the last column of Table 1.

We have the following possibilities for alternate flattenings to which to refer the estimated zone mean anomalies: (1) the flattening which minimizes the correlation of the Δg_{sh} with latitude; (2) the flattening of hydrostatic equilibrium, 1/297.34 [*Bullard*, 1948]; and (3) the flattening of the solution itself.

To determine the flattening which minimizes the correlation of Δg_{sh} with latitude, separate solutions were made in the conventional manner for each of seven elevation groups, and the results combined with weights in proportion to the occurrence of each elevation on the total Earth's surface. The results are shown in Table 4.

The resulting flattening of 1/297.33 is remarkably close to the flattening of hydrostatic equilibrium. This agreement may be significant; it certainly seems logical that correlation of the gravity anomaly with elevation should be a function of departure from the hydrostatic figure.

For the minimum correlation and hydrostatic flattening, $\Delta\alpha_j = -(1/297.3 - 1/297.0)978049 = +3.36$ mgal, and

$$\Delta g_s = r_s \Delta g_0 + \sum s_{sh} [\Delta g_h + 3.36 (\sin^2 \phi_s - \overline{\sin^2 \phi^h})] \tag{8}$$

The Δg_s are again shown in Table 3. The solution: $\Delta\gamma_e = -8.56$ mgal, or $\gamma_e = 978040.4$ mgal, and $\Delta\alpha = +12.70$ mgal, or $f = 1/298.15$.

For Method 3, in which the estimated zone mean anomalies are referred to the flattening of the solution itself, $\Delta\alpha_j = \Delta\alpha$, and so must remain as an unknown in the observation equations, which become

$$\begin{aligned} v_s = {} & r_s[\Delta g_0 - (\Delta\gamma_e + \Delta\alpha \sin^2 \phi_s)] \\ & + \sum_h s_{sh}[\{\Delta g_h + \Delta\alpha(\sin^2 \phi_s - \overline{\sin_2 \phi^h})\} \\ & - \{\Delta\gamma_e + \Delta\alpha \sin^2 \phi_s\}] \\ = {} & r_s \Delta g_0 + \sum_h s_{sh} \Delta g_h - \Delta\gamma_e \\ & - \Delta\alpha(r_s \sin^2 \phi_s + \sum_h s_{sh} \overline{\sin^2 \phi^h}) \end{aligned} \tag{9}$$

The result is: $\Delta\gamma_e = -20.8$ mgal, or $\gamma_e = 978028.2$ mgal, and $\Delta\alpha = +61.4$ mgal, or $f = 1/302.6$.

The Δg_s computed after the solution using $\alpha_j = +61.4$ mgal are shown in Table 3.

It seems evident from the unreasonably large change yielded by Method 3 that correlation of the gravity anomaly with elevation is not a function of departure from the mean Earth ellipsoid, the best fit to the geoid which is the traditional objective of geodesy. This conclusion suggests that though 1/298.15 is the flattening which best fits the external gravitational field, the best geophysical reference might be one with the hydrostatic flattening 1/297.34. Assuming that the mean attraction should remain the same, the equatorial term for this 'geophysical' standard formula would be

$$\gamma_e = 978040.4 \quad [1 + \tfrac{1}{3}(1/297.34 - 1/298.15)]$$
$$= 978045.9 \text{ mgal.}$$

A corroboration of this difference between the hydrostatic and external field flattenings was found by fitting a straight line formula, $\Delta g = a + bh$, to the Δg_h in Table 1, weighting each in proportion to the occurrence of its elevation on the total Earth's surface. The best fit was $\Delta g = +13.17 + 2.44h$ mgals, for h in thousands of feet, or $+13.17 + 0.0080h$ for h in meters. Assuming that this correlation applies to the second degree zonal harmonic of the topography, as found by *Prey* [1922], we get for the corresponding coefficient of gravity

$$0.0080(1134 - 1037 \times 1.03/2.67) = +5.88 \text{ mgal,}$$

$$\text{or} \quad \Delta f = -3/2 \cdot 5.88/978049 = -0.0000090;$$

$$\text{while } 1/298.15 - 1/297.34 = -0.0000092.$$

To evaluate the accuracy of the solution, we must consider the two reasons why the estimated zone mean anomalies differ from 0: (1) because the true zone mean will differ from 0; and (2) because the estimate will differ from the true zone mean. The first difference is due to the higher degree zonal harmonics $P_n(\sin\phi)$ in the gravitational field. An estimate was made of the variances of the harmonic degrees by a covariance analysis; the portion of each variance due to the zonal harmonic was assumed to be $1/(2n + 1)$; and the variances of the zone means were then computed as $\Sigma\sigma^2{}_n[\overline{P_n(\sin\phi)_z}]^2$ using the even degrees only, since the odd degrees cancel each other out in meaning the northern and southern hemisphere zones. The resulting element variances $\sigma^2\{\Delta g_z\}$ are given column 2 of Table 5.

TABLE 5 - *Variances of 10° zone means*

Zone	Element variance $\sigma^2\{\Delta g_z\}$	Estimate variance $\sigma^2\{\hat{\Delta g_z} - \Delta g_z\}$	Total	$\frac{0.75}{a_z}$
° °	mgal²	mgal²	mgal²	
0–10	2.4	1.3	4	4.3
10–20	2.7	1.4	4	4.4
20–30	3.3	1.3	5	4.7
30–40	3.6	1.4	5	5.2
40–50	4	1.6	6	6.1
50–60	5	2.1	7	7.5
60–70	7	3.3	10	10.1
70–80	12	5.8	18	16.1
80–90	36	15.8	52	49.6

The estimate variances $\sigma^2\{\widehat{\Delta g_z} - \Delta g_z\}$ were estimated on the assumption of randomness between 10° blocks, which is incorrect, but consistent with the assumption of randomness between 10° zones already made in the least-squares solutions. Using the 10° block system of ***Zhongolovich*** [1952], the portion of each block observed was computed. The variances of the anomaly estimates based on elevations were computed for (1) a sample of all the 1° squares; and (2) a sample of all 10° squares more than 70 pct observed. The former variance was found to be about 1000 mgal²; the latter, 110 mgal². Thus, for example, for a zone consisting of 7200 1° squares, the contribution of a single 1° × 1° square estimated anomaly to the zone variance would be $1000/(7200)^2 = 1/52{,}000$ mgal²; but for a 10° × 10° square estimated anomaly the contribution would not be 100/52,000, but $110/(72)^2 = 1/47$ mgal². For cases in between the one and 70 pct unobserved, values were interpolated for the variance $\sigma^2\{\Delta g_s\}$, where the s denotes the portion of the 10° square unobserved. The total estimate variance, then, for a zone of n 10° blocks will be $(1/n^2)\Sigma_i s_i^2\sigma_i^2\{\Delta g_s\}$. This solution assumes, of course, that the contribution of 1° × 1° squares with gravity observations is negligible.

The estimate variances for each zone are given in the 3rd column of Table 5.

Knowing the variances of the zone means Δg_z, we thus can compute the variances of the $\Delta\gamma_e$ and $\Delta\alpha$ derived from them; for example, expressing $\Delta\gamma_e$ as $\Delta\gamma_e = \sum c_z \Delta g_z$, then

$$\sigma^2\{\Delta\gamma_e\} = \sum c_z^2 \sigma^2\{\Delta g_z\}.$$

The zone variances were computed with the purpose of using them for weighting; however, note that they are almost inversely proportional to the zone areas; so nearly so, that the change from weighting according to area would make negligible difference.

The flattenings obtained from terrestrial gravimetric observations are not directly comparable to those obtained from the precession of satellite nodes, because the satellite passes through only a portion of the Earth's gravitational field and hence will give a best fitting answer for only this portion. If we know the higher zonal harmonics of even degree, we can estimate the difference of a flattening derived from satellite observations. The coefficient for a zonal harmonic of degree n will be

$$a_n = (2n+1)\int_{-\pi/2}^{\pi/2} \Delta g_z P_n\{\sin\phi\}\cos\phi\, d\phi \quad (10)$$

where Δg_z is the mean anomaly for the infinitesimal zone $d\phi$. The zonal harmonics a_4 and a_6 were computed from the Δg_z based on $f = 1/297.3$ (see Table 3), using as a unit of area the 10° square of *Zhongolovich* [1952], and using his averaged harmonics $\overline{P_n}$

$$a_n = \frac{2n+1}{410}\sum_z n_z \Delta g_z \overline{P_n}(\sin\phi_z) \quad (11)$$

where n_z is the number of 10° blocks in each zone: 72 in 0°–10°, 68 in 10°–20°, etc. The values found:

$$a_4 = +5.05 \text{ mgal};$$

$$a_6 = +3.40 \text{ mgal}.$$

A spherical harmonic component of the gravitational acceleration on the geoid of degree n will have a corresponding acceleration at altitude $h = r - R$ which is $(R/r)^{n+2}$ times as great, where R is the Earth's radius. For terms of interest in the present problem

$$a_{2.h} = (R/r)^4 a_2, \qquad a_{4.h} = (R/r)^6 a_4,$$

$$a_{6.h} = (R/r)^8 a_6 \quad (12)$$

The apparent change $\delta a_{2.h}$ in the second-degree harmonic coefficient from measurements, direct or indirect, of the gravitational field limited to a zone should be the best least-squares fit of the second-degree harmonic to the higher degree even zonal harmonics in the zone. For altitude h between latitudes $+\phi_i$ and $-\phi_i$ we therefore have

$$\frac{d}{d(\delta a_{2.h})} \cdot \left(\int_{-\phi_i}^{+\phi_i} [\delta a_{2.h} P_2 - (a_{4.h} P_4 + a_{6.h} P_6 + \cdots)]^2 \cos\phi\, d\phi\right) = 0$$

or

$$\int_{-\phi_i}^{+\phi_i} P_2[\delta a_{2.h} P_2 - (a_{4.h} P_4 + a_{6.h} P_6 + \cdots)] \cdot \cos\phi\, d\phi = 0 \quad (13)$$

The integrals being symmetrical about the equator, we can set

$$\delta a_{2.h} = \frac{a_{4.h}\int_0^{\phi_i} P_2 P_4 \cos\phi\, d\phi + a_{6.h} \cdot \int_0^{\phi_i} P_2 P_6 \cos\phi\, d\phi + \cdots}{\int_0^{\phi_i} [P_2]^2 \cos\phi\, d\phi} \quad (14)$$

or

$$\delta a_{2.h} = A(\phi_i) a_{4.h} + B(\phi_i) a_{6.h} + \cdots$$

$$\left(\frac{R}{r}\right)^4 \delta a_2 = A(\phi_i)\left(\frac{R}{r}\right)^6 a_4 + B(\phi_i)\left(\frac{R}{r}\right)^8 a_6 + \cdots$$

$$\delta a_2 = A(\phi_i)\left(\frac{R}{r}\right)^2 d_4 + B(\phi_i)\left(\frac{R}{r}\right)^4 a_6 + \cdots \quad (15)$$

$A(\phi_i)$ and $B(\phi_i)$ are functions of the orbital inclination only, while r is a function of the eccentricity and semi-major axis. To solve the problem we need merely the inclination and the mean values of $1/r^2$, $1/r^4$, $\cdots$ for the period of time from which the determination of flattening was made.

For example, for a satellite of inclination 34°, semimajor axis 8650 km and eccentricity 0.19, we get $A(\phi_i) = -0.414$, $B(\phi_i) = +0.092$, and mean $1/r^2 = 1/(8.56)^2$ in units of 1000 km. Using the values $a_4 = +5.05$ mgal and $a_6 = +3.37$ mgal, $\delta a_2 = -1.16 + 0.09 = -1.07$ mgal. Whence $\Delta\alpha = -1.61$ mgal, or $\Delta f = +0.00000165$, and $f = 1/298.00$

A Study of the Use of Atmospheric-Electric Measurements in Fog Forecasting

G. P. SERBU AND EVA MAE TRENT

Abstract—A statistical study of atmospheric-electric and pertinent meteorological data collected in Argentia, Newfoundland, from January through September 1955, shows that fogs produce a decrease in the electrical conductivity with a concurrent increase in potential gradient. A quantitative analysis of the data shows that during fog (horizontal visibility less than ½ mile, ceiling less than 200 ft) the average conductivity was less than 0.65 times the monthly mean 92 pct of the time and the average potential gradient was more than 2.0 times the monthly mean 87 pct of the time. From one to two hours preceding the onset of fog the conductivity decreased and the potential gradient increased in about 70 pct of the events. One hour prior to dissipation of fog conductivity increased and potential gradient decreased in 75 pct of the events. Similar studies should be made in additional areas to determine whether the Newfoundland results are unique or may be encountered more generally.

Introduction—The lowering of the electrical conductivity of the atmosphere in thick fog has been reported by several authors; notably, *Gockel* [1917], and *Scrase* [1933]. *Reiter* [1956] working in the northern Bavarian Alps reported, "Certain rules were derived pertaining to the forecast of formation, dissolution, and stability of fog and stratus from the behavior of the electric magnitudes."

George [1951] gives the following definition of fog: "When a cloud consisting of minute water droplets or ice crystals envelops the observer and restricts his horizontal visibility to 1000 m or less, the international definition of fog has been satisfied." For purposes of this paper the definition of fog is further restricted to conditions in which the horizontal visibility is less than ½ mile and the ceiling is less than 200 feet. These restrictions coincide with minimum meteorological conditions for the landing and take-off of aircraft at the U. S. Naval Station, Argentia, Newfoundland.

Of the atmospheric-electric quantities, conductivity is the most important index of local variations. The atmospheric conductivity is due chiefly to small ions which are produced by cosmic radiation and by radioactive matter in the Earth and air. The presence of contaminants, plentiful in continental air masses, causes the small ions to lose their charge to less mobile nuclei, thereby reducing the conductivity. Hence local pollution sources and meteorological conditions determine the conductivity within the exchange (or mixing) layer, and cause a local diurnal variation in conductivity which corresponds to the daily turbulence cycle [*Sagalyn*, 1956].

Potential gradient is an important index of world-wide effects. *Mauchly* [1926] found that the surface potential gradient over the oceans at different longitudes varies diurnally with universal time. *Whipple* [1929] later showed that this universal diurnal variation with a maximum at 19h GMT correlates with a similar one in world-wide thunderstorm activity. The diurnal variation in potential gradient at land stations is more complex, the local variations due to conductivity changes frequently obliterating the universal variation.

In 1954, the U. S. Naval Research Laboratory originated a research program to evaluate atmospheric-electric measurements in terms of universal and local effects and to correlate these measurements with meteorological phenomena. Several stations were established to make continuous measurements of atmospheric-electric quantities. The U. S. Naval Station, Argentia, Newfoundland, was chosen as a site for one of the stations because of its climatology, its remoteness from regions of industrial contamination, and the availability of weather data. Continuous recordings of surface potential gradient and both positive and negative conductivities were made.

The same data were used also by *Minton* [1955], who reported the use of the changes in conductivity and surface potential gradient as valuable aids to the operational forecasting of fog at Argentia. He formulated empirical rules and used them to forecast the onset, duration, and dissipation of fog from one to six hours in advance. Since banks of advection fog over the water surrounding Argentia advance and recede, and rise and lower over the airfield in an erratic manner, accurate short-term forecasting is both necessary and difficult.

Methods of measurement—The atmospheric conductivity is measured with a Gerdien-type cylindrical condenser mounted one meter above the ground. A voltage is applied to the outer electrode and the current to the central electrode is measured with a vibrating-reed electrometer. Air is drawn through the chamber with a velocity high enough that the change of current with applied voltage is linear and proportional to the conductivity. Both polar conductivities are recorded alternately from a single instrument by using a one-hour cycle timer which applies a constant positive voltage to the chamber for nearly half an hour, a negative voltage of equal amplitude for the next similar interval, and a zero-reference potential for a few minutes. The system is carefully calibrated and the overall accuracy is ±5 pct.

The surface potential gradient is measured with a grounded-rotor induction-type electric field meter, EFM, identical to that described by *Clark* [1957] for airborne use. Since the EFM is mounted one meter above the ground in a wooden box, the presence of the box augments the measured field as compared to that on a flat portion of the Earth's surface. This geometric augmentation factor was experimentally determined to be 2.15 by comparing the measured field at the box with simultaneously measured values from another EFM mounted flush with the Earth's surface. Hourly checks of the EFM zero and daily system-gain checks permit an overall accuracy of ±10 pct in the potential gradient measurement.

Sample records of potential gradient and conductivity are presented in Figure 1. The potential gradient $\partial V/\partial Z$ is related to the vertical (upward) electric field component E_z by the expression $\partial V/\partial Z = -E_z$ where both are in volts per meter. Since the fair-weather electric field is normally negative, the positive potential gradient is preferred for plotting. Total conductivity λ_T is the sum of the two polar conductivities. In the figure, the potential-gradient trace is concurrent with the conductivity trace immediately below it. The second conductivity trace is presented to illustrate the difference between a smooth, slowly changing trace and a 'jagged,' rapidly changing one. In subsequent figures the plotted values of the atmospheric-electric variables are hourly averages.

The station at Argentia is shown in Figure 2. The airfield is to the right with runways about a quarter of a mile away; to the left is Placentia Bay which opens to the Atlantic Ocean some forty miles to the south. The frame structure on the left is a sea-spray wall situated to protect the instrumentation during storms. Adjacent to the wall is the housing for the conductivity meter and recorders. The box on the right contains the electric field meter which measures surface potential gradient. An automatic calibration plate can be seen just to the left of the EFM.

The meteorological data used in this paper are taken from the *Hourly Sequence Weather Reports* prepared by the Argentia Fleet Weather Central which is located one-half mile east of the station. Reports are made hourly at four minutes preceding the hour unless special conditions, such as restricted visibility and ceiling, necessitate more frequent reports. The recorded horizontal visibility is based on the observer's ability to discern objects at known distances. During indefinite ceiling conditions, the height of the lowest cloud base is estimated visually. Symbols used in the *Hourly Sequence Weather Reports* are presented in abbreviated form in Table 1.

Data and results—The conventional forecasting of fog at Argentia is dependent primarily upon the analysis of the air-mass trajectory and the frontal positions. The cold Labrador current off the east coast and its component along the Grand Banks to the south in conjunction with the warm

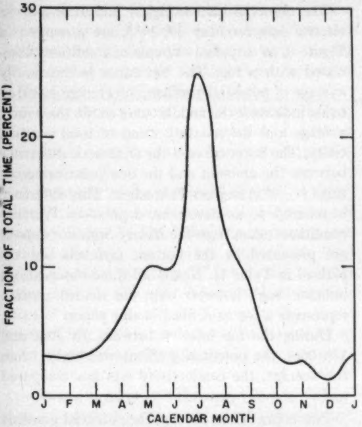

FIG. 3 – Yearly cycle of monthly averages of fog occurrence at Argentia, Newf. [Raymond, 1954]

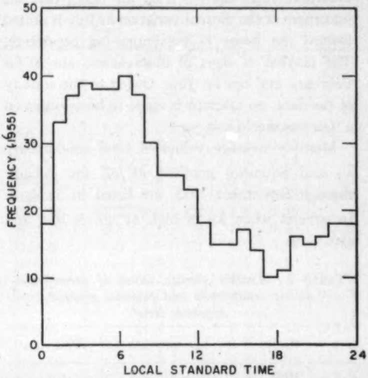

FIG. 4 – Variation in fog occurrence with time of day at Argentia, 1955

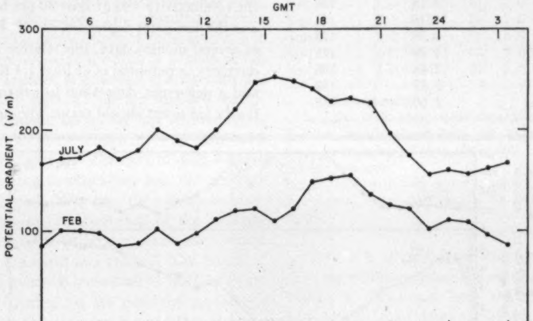

FIG. 5 – Comparison of diurnal variations of potential gradient for February and July, 1955 at Argentia

Gulf Stream provide an ideal fog-forming situation along the southern and eastern coast lines. In spring and early summer the differential heating rate between sea water and air causes a strong cooling in the lower layers of the air mass; consequently, fog forms frequently [*Taylor*, 1917]. In the fall and winter the reverse is true and fog is less frequent. The effect of this mechanism is illustrated by the data compiled by *Raymond* [1954] in Argentia and presented here as Figure 3. July is particularly noteworthy in that fog occurs 25 pct of the time.

The histogram of Figure 4 represents the number of times fog occurred in each hour interval of the day for 1955. Fog occurred most frequently in the early morning, local standard time, LST, 3½ hr behind GMT.

The diurnal variations of the potential gradient for February and July 1955 at Argentia are illustrated in Figure 5. The peaks of the two curves occur four hours apart; nevertheless there is general agreement with the universal diurnal variation. It is inferred from the figure that the maximum of the diurnal variation in July is shifted toward the hours of maximum fog occurrence. The number of days of observations are 20 for February and ten for July. Owing to the scarcity of the data, no attempt is made to be selective on a 'fair-weather' basis.

Monthly average values of total conductivity $\bar{\lambda}_T$ and potential gradient $\overline{\partial V/\partial Z}$ for January through September 1955, are listed in Table 2. In general when $\bar{\lambda}_T$ is high $\overline{\partial V/\partial Z}$ is low, and vice versa.

TABLE 2 – *Monthly average values of atmospheric-electric conductivity and potential gradient, Argentia, Newf.*

Month	$\bar{\lambda}_T$ (10^{-14} mho/m)	$\overline{\partial V/\partial Z}$ (v/m)
1955		
January	4.25	127
February	3.34	112
March	3.18	146
April	4.36	128
May	4.35	128
June	4.39	125
July	2.48	198
August	2.87	188
September	2.60	188

The observed meteorological and atmospheric-electric data for May 29, 1955, are presented in Figure 6, as a typical example of conditions associated with a fog. The top curve is the hourly average of potential gradient, its average for May being indicated; the middle curve shows the hourly average and the monthly mean of total conductivity. The lower curve is the arithmetic difference between the ambient and the dew-point temperatures $t - d$ in degrees Fahrenheit. This difference is referred to as dew-point depression. Weather conditions taken from the *Hourly Sequence Reports* are presented at the bottom (symbols are explained in Table 1). Nearly all these observations indicate 'fog'; however only the shaded portion represents a fog as defined in this paper.

During the fog interval between 7h 30m and 13h 06m, the potential gradient was higher than the average, the conductivity was low compared to $\bar{\lambda}_T$, and the dew-point depression was 0°.

Two hours before the fog, the potential gradient was variable about its monthly average, but increased prior to the fog onset. At the same time the conductivity was at least 30 pct below average and the dew-point depression was 1°. From analysis of several months data, this relative value of conductivity, a potential of at least 1.4 times average, and a dew-point depression less than 2°, indicate that a fog event should occur. The lowering trend

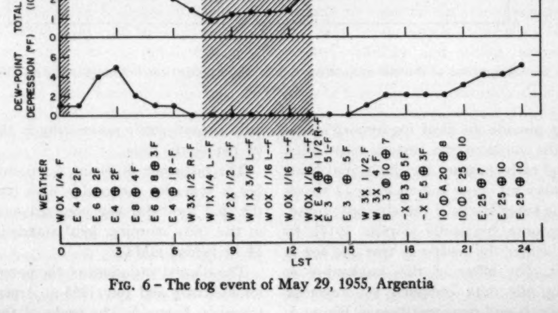

FIG. 6 – The fog event of May 29, 1955, Argentia

in the dew-point depression indicates an increase in water content, which is necessary but not sufficient for fog formation. This is borne out by the fact that frequently the dew-point depression is less than 2° in the absence of fog.

During the fog event, one hour before dissipation, conductivity started increasing, indicating dissipation even though the dew-point depression remained at 0°.

A summary of the statistical analysis of short-term (<5 hr) fog events is presented in the upper part of Table 3. The following conclusions are evident. In fog, the average conductivity level $\bar{\lambda}_f$ is generally less than 65 pct of the monthly mean, and the dew-point depression is always less than 2° and is generally 0°. The indications of the onset of fog, that is conductivity decreasing by at least 30 pct of $\bar{\lambda}_T$ accompanied by the dew-point depression approaching zero, occur from a half to two hours in advance. The indication of dissipation, conductivity increasing toward the average, occurs in most of the events at least one hour in advance despite the frequent absence of any rise in the dew-point depression above zero even after the fog has dissipated. The potential-gradient data are missing during many of these events, but when data are available the ratio of average in fog to monthly average is generally greater than 2.0 (approximately full-scale on the recorded trace).

Fogs at Argentia frequently last for five hours or more. These extensive fogs are very dense and generally homogeneous. The data of July 3–4 are typical of a long homogeneous fog and are presented in Figure 7. Note that the average conductivity level in fog is about half of the monthly mean and that the variations about the average level in fog are slight and gradual. The summary of long-term events is presented in the lower part of Table 3. During fog the potential gradient is almost always at least twice the monthly average; prior to onset, the potential gradient starts rising above average, and approaches the average before dissipation. A comparison of the two parts of Table 3 shows the similarity of the average levels of atmospheric-electric quantities in both long and short fog events. The table summarizes all the available atmospheric-electric data pertaining to fog for the ten months covered by this investigation.

..., data missing.

In July 1955, there were an additional 167 hr of fog for which there were no atmospheric-electric data; meteorological data show that there was fog 27 pct of the time.

[a] Divided into two groups; upper part, less than five hours; lower part, equal to or more than five hours.

Occasionally in long-term fogs small openings, or 'holes,' occur for intervals ranging from fifteen minutes to one hour. During these periods, aircraft are permitted to land and take off; consequently, it is advantageous to forecast whether or not a fog will have holes. The event of February 23, Figure 8, illustrates how inhomogeneous fogs (those with holes) differ electrically from homogeneous fogs (Fig. 7). The average level of conductivity during the February 23 event was about half of the monthly mean; however, large and abrupt variations about $\bar{\lambda}_f$ occurred. This is in contrast to the smooth and gradual changes shown in Figure 7. An examination of the conductivity records of the two events shows a difference in the fine structures; the trace of July 4 is smooth and slowly changing, while the trace of February 23 is jagged and changing rapidly from minute to minute as shown in the bottom trace of Figure 1. These variations are masked on the later figures by hourly averages.

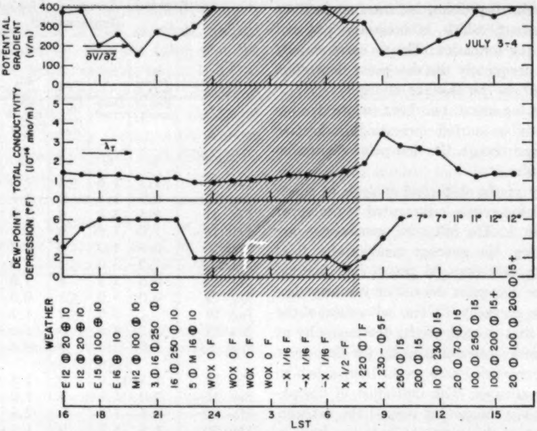

FIG. 7 – Example of homogeneous long-term fog event July 3–4, 1955, Argentia

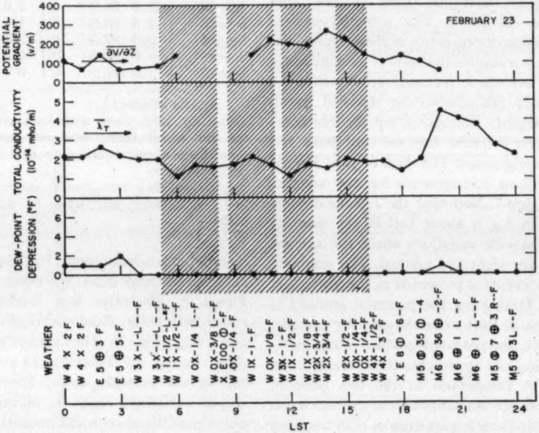

FIG. 8 – Example of inhomogeneous long-term fog event February 23, 1955, Argentia

The meteorological data for February 23 reveal that holes appeared in the fog at approximately 08h 30m, 11h 30m, and 14h. A rather abrupt rise of some 30 pct in λ_t occurred one to two hours prior to each of these holes. The potential-gradient data for such fogs are too sparse for analysis, but observers in the field have indicated that the behavior of potential gradient assists in determining if the conductivity increase (or fluctuation) is to be used for forecasting a hole or dissipation.

Discussion—Within the limits of our definition of the presence of fog, that is, ceiling below 200 ft and horizontal visibility less than a half mile, the presented data show a high degree of correlation between the atmospheric-electric measurements and the occurrence of fog. During such fog the values of dew-point depression, potential gradient, and conductivity are found to lie within certain limits. The high level of positive correlation shown in Table 4 illustrates the validity with which the limits can be chosen on the basis of a statistical study such as this one.

The technique of using atmospheric-electric variables to forecast fog depends on trends in the variables prior to reaching the limits chosen. Normalized to the monthly average, values of the variables for fog events from January through September, presented in Figure 9, show trends before onset and before dissipation. As previously stated, the potential gradient data are missing for many of the short events; therefore a normalized curve of the gradient for such events would be inconclusive. Between two and three hours before onset, the dew-point depression is within 2°F and decreasing; the potential gradient is increasing and reaches a relative value of 1.4 at -2 hours; the conductivity is decreasing and reaches 0.70 at -1 hour for short events and -3 hours for long events. These relative values of potential gradient and conductivity do not normally occur in fair weather, hence are noteworthy. The dew-point depression remains below 2° until sometime after dissipation while the potential gradient shows a lowering trend and the conductivity a rising trend for an hour before dissipation. On the 'wind rose' the point from which the direction lines originate in each case is the average wind speed in knots, and the lengths of the direction lines are proportional to the number of observations of specific wind directions. The average wind speed and direction are presented to show that such data are inconclusive for purposes of short-term fog forecasting.

Suggested mechanisms—Atmospheric conductivity is due primarily to singly charged small ions of relatively high mobility in the size range 10^{-7} cm and less, where

$$\lambda = nek$$

Here n is the small-ion density, e the elementary charge, and k the mobility. The conductivity reduction in fog is due to a decrease in small-ion density caused by the loss of small ions by diffusion to capturing fog droplets. This, however, does not explain the lowering of conductivity which has been observed prior to fog. Other, smaller

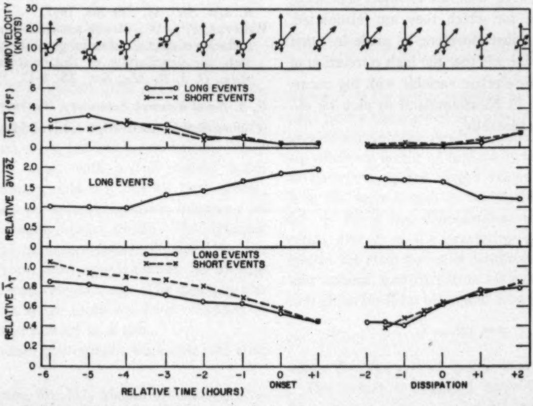

FIG. 9 – Normalized values of atmospheric-electric and pertinent meteorological variables

particles which are known to play a role similar to that of fog droplets in reducing λ include Aitken particles (10^{-7} to 10^{-5} cm) and haze particles (10^{-5} to 10^{-4} cm). Since the largest particles are activated first, the Aitken particles do not normally constitute the active fog condensation centers and are too small to produce appreciable scattering of visible light according to the Mie theory. However, the larger haze particles participate in both processes, according to *Junge* [1958]. Thus, the observed conductivity decrease prior to fog can be attributed to an increase in the density of the Aitken particles or an increase in the size of the larger particles.

The density increase could be explained by advection of air in which the aerosol density and size are changing with horizontal position, while the size increase could be due to cooling of the air *in situ* causing condensation. Such cooling could also take place during advection, thus creating the required aerosol size distribution with distance. It is recognized that the activation of Aitken particles as condensation centers implies an initial absence of haze and larger particles, perhaps due to the remoteness of the site from industrial pollution sources, or more probably to a prior precipitation of these particles in the sustained high relative humidity environment.

Summary—The trends of atmospheric-electric variables may be used to assist conventional meteorological methods in forecasting fog more accurately at Argentia. The quantitative limits placed upon these variables are certainly dependent upon the locale for which they are formulated. Similar studies must therefore be made in other areas to determine whether the high correlation of each atmospheric-electric variable with fog occurrence is unique in Newfoundland or may be encountered more generally.

Acknowledgments—The authors are indebted to J. F. Clark and J. H. Kraakevik of the U. S. Naval Research Laboratory for valuable discussions concerning the preparation of this paper, and to C. R. Hamilton for his contribution in designing and installing the station. The authors express their gratitude to the personnel of the U. S. Fleet Weather Central, Argentia, for assistance in the collection of data.

Rainfall Measurement by Radar Using Photographic Integration Techniques*

H. W. HISER, H. V. SENN, AND L. F. CONOVER

Abstract—Methods have been devised to estimate areal rainfall amounts as portrayed by radar. This is accomplished by a continuous photographic integration of the plan position indicator (PPI) scope over periods of one or more hours giving the hydrologist almost immediate information on the precipitation falling on an area of over 30,000 sq mi. These investigations have developed echo-density contour maps which correlate favorably with isohyetal maps. The limitations and capabilities of present radar systems for purposes of radar integration of rainfall also have been evaluated.

Introduction—The use of radar as a meteorological tool for determining precipitation patterns qualitatively in recent years has led to many attempts to also determine the quantity of precipitation over the area of radar coverage. Investigations have been made by the Massachusetts Institute of Technology, Canadian Army Operational Research Group, Thunderstorm Project, Illinois State Water Survey, McGill University, University of Florida, Texas A & M College, and others. The first known use of photographic integration of rain echoes on radar, which is the basic method used in the research reported here, was made by *Rockney* [1954]. All such investigations were immediately faced with many serious problems both in obtaining the radar precipitation data and in providing reasonably accurate rainfall sampling for correlation purposes over the area of radar coverage. Only a few of these problems have been solved in the present study, but the techniques used have led to tentative solutions to other, especially equipment, problems and increased optimism for rainfall measurement by radar [*Hiser* and *Conover*, 1956] [*Hiser* and others, 1957].

Equipment used—Most of the data for this study were obtained on a 10.7-cm wave length, Navy model SP-1M radar with a 3.2° conical beam (antenna diameter 2.44 m), 750 kw peak power, and 635 pulses per second repetition frequency on its one microsecond pulse length. The dynamic range and the minimum detectable signal for the receiving system were approximately 32 db and 4.0×10^{-13} watts respectively. The antenna was located 135 ft above mean sea level, elevated to +0.5° tilt, and rotated at 3 rpm.

The integrated photographs were obtained with two 8 × 10-inch plate back cameras mounted on Navy model VD-2, seven-inch PPI repeater scopes. The use of two integrator cameras permitted simultaneous comparisons of different photographic materials, repeater operation techniques, and camera aperture settings. The camera shutters were left open continuously for the entire period of integration which ranged from one to six hours. All gain and intensity settings were calibrated and recorded so that optimum conditions could be reproduced as accurately as possible from day to day. Processing of the 8 × 10-inch papers and films was also carefully controlled so that a constant gamma was obtained for each photographic material.

Theoretical considerations—Theoretical 'Minimum detectable rainfall rates' and 'receiver saturation rainfall rates' for the SP-1M, Table 1, were computed by the use of the above radar parameters and the equation of *Marshall* and others [1947].

$$P_r = P_t \frac{\pi^4 A h}{8 r^2 \lambda^4} \frac{(n^2 - 1)^2}{(n^2 + 1)^2} Z \tag{1}$$

where P_r is the power received in watts; P_t is the peak power transmitted in watts; A is the effective area of the antenna in square meters, based upon an efficiency factor of 0.55; h is the pulse length in meters; r is the target range in kilometers; λ is the wave length in centimeters; $(n^2 - 1)^2/(n^2 + 1)^2$ is the dimensionless refractive index term; and Z is the scattering quantity which relates the sixth power of raindrop diameters in a unit volume, mm^6/m^3, to rainfall rates. The equation given for Z by *Gunn* and *East* [1954] was used

$$Z = 353\, R^{1.52} \tag{2}$$

where R is the rainfall rate in mm/hour.

The values in Table 1 have been converted from metric units given by (1), to nautical miles

* Contribution No. 211, Marine Laboratory, University of Miami, Coral Gables, Florida.

TABLE 1 – *Theoretical minimum detectable and receiver saturation rainfall rates for SP-1M radar on one microsecond pulse*

Range from radar	Min. detectable rainfall rate	Receiver saturation rainfall rate
naut mi	inch/hr	inch/hr
10	....	0.18
20	....	0.43
30	....	0.74
40	0.01	1.05
50	0.01	1.40
60	0.02	1.80
70	0.02	2.02
80	0.02	2.60
90	0.03	3.10
100	0.03	3.50

and inches per hour. These minimum detectable rates and saturation rates are based upon the assumption that the precipitation target completely fills the radar beam in the plane normal to the axis along which the beam is directed and to a depth of at least one-half pulse length in range. It is believed that the actual receiver saturation rainfall rates and the minimum detectable rates for the SP-1M radar used in this research were close to these calculated values.

Methods of analysis—The densities of echoes were read on a Welch Densichron transmission-type densitometer which was calibrated in accordance with standards of the American Standards Association (ASA). Density (or opacity) was then compared with the actual rainfall recorded by raingages during the period of integration. In this research, each integration or a series of integrations is treated as an entity in order to eliminate the effects of day to day variations in the radar and photographic processes.

The 'point' method, in which the rainfall amounts were correlated with the film's echo density measured directly over the raingage location, was used extensively. Densities were read using overlays which contained the positions of 71 recording raingages within 100 naut mi of the radar. This method suffers from the inability to determine the raingage locations accurately on the integration film, because of certain non-linearities and day to day variations in the scale of the radarscope, as well as serious difficulties in accurately computing precipitation-time relationships. Both are extremely critical requirements because of the high rainfall (and therefore density) gradients produced by the showery precipitation typical of the experimentation area.

An 'areal' method was developed in which rainfall amounts are used to produce an isohyetal map and densities are read from the film onto a grid system to form a density contour map which is compared with the isohyetal map. This method smooths out errors that are inherent in the point method, since large numbers of density readings are used to produce the contours. The grid system is also easily adaptable to fast and accurate data transmission by teletype or facsimile under operational conditions.

Figure 1 shows one of the integrations with a map of Florida superimposed. This photograph was made on Fine Grain Positive film during the three hour-period 14h 00m – 17h 00m EST, February 26, 1957. Figure 2 is an enlarged echo-density contour map which illustrates the areal method of analysis. It was constructed by reading echo densities within the rectangle shown to the north of the radar station in Figure 1. Density readings were taken in each of the grid squares where an echo was present. The echo contours are labeled in ASA density. Rainfall totals for the three-hour period of integration are plotted at the gage locations, solid dots, and 'NR' indicates no record.

Problems involved—The density of an echo over a raingage at a particular range is not only a function of the rainfall rate and duration but also of the following parameters:

(a) Radar: Wave length, power transmitted, pulse length, antenna gain, normal range attenuation of radar signals, minimum detectable signal, dynamic range of the receiver, antenna rotation speed, and pulse repetition frequency.

(b) Precipitation: Size, shape, composition, and motion of particles; height of detectable cloud; and other factors such as vertical wind shear and humidity differences between echo level and ground.

(c) PPI scope: Age and other characteristics of the cathode ray tube (CRT) and other components, dynamic range of the video amplifier for the scope, intensity settings, focus, range increments used, and writing speed of the sweep.

(d) Photographic: Aperture of camera iris, length of exposure, characteristics of the light sensitive material used, and processing techniques.

It appears obvious that direct correlations between echo densities and rainfall amounts which are obtained over a period of time for a given radar are applicable only to that radar, and even then are subject to some change as radar and repeater systems age and change or are modified. Results obtained with the SP-1M radar under varying

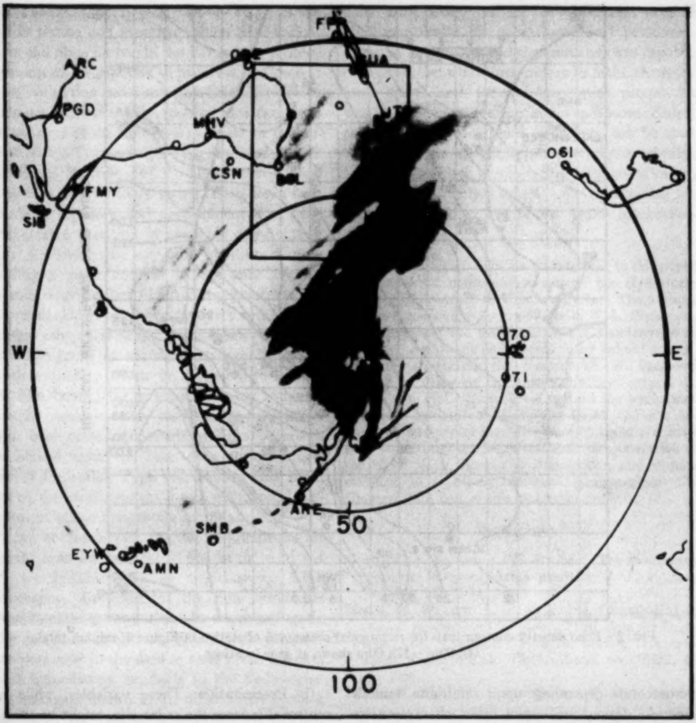

FIG. 1 - Photo-integration 365A, 14h 00m - 17h 00m EST, Feb. 26, 1957, with map of southern Florida superimposed

meteorological conditions and carefully controlled research procedures indicate that a definite relationship can be established between echo density and total rainfall for a given radar. However, they also revealed a number of radar and other parameters which should be optimized for purposes of rainfall integration as well as for the advancement of radar as a general meteorological tool.

The receiver saturation rainfall rates for the SP-1M and most other radars are a serious handicap to photographic integration. When these limiting rainfall rates are exceeded there is no way to ascertain the true intensity of the rainfall. Because the receiver saturation rainfall rate increases with range from the radar (Table 1), the most reliable radar-rainfall correlations obtained by this project are those beyond 40 or 50 miles range where the saturation problem is less important.

Procedures and equipment recommended for optimum results in integrating rainfall by radar—The following five conditions should be attained.

(a) Radar: The wave length must be short enough to detect most precipitation out to near 100 mi and to provide economy of power and antenna size characteristics; but it must be long enough so that there is no appreciable precipitation attenuation. At present a wave length near 10 cm appears best. The pulse length should be short enough to provide good echo resolution and long enough to provide enough power for desired minimum detectability of light rain: one to four

NAUTICAL MILES RANGE FROM RADAR

FIG. 2 – Echo density contour map for rectangular area north of station in Figure 1, rainfall totals 14h 00m – 17h 00m shown at gage locations

microseconds depending upon minimum rainfall detection desired and upon other characteristics of the radar.

Receiver and display characteristics should be such that a dynamic range on the order of 60 to 80 db is available to portray precipitation rates from a few hundredths of an inch per hour at ranges in excess of 100 mi to over ten inches per hour at a range of ten miles without overloading or saturating. Such a receiver should have a logarithmic output in order to prevent saturation of the cathode-ray tubes and other indicator components. It should also incorporate exponential range and sweep writing speed correction circuitry to permit echoes representing equal rainfall intensity to be portrayed at equal intensity on the face of the CRT regardless of their ranges. Both the receiver with a large dynamic range and the range correction device are under development at the University of Miami.

(b) Precipitation: These variables, while not controllable from the radar site, might be studied more effectively and identified more readily by use of improved radars having the optimum characteristics mentioned above.

(c) PPI scope: The aging of the CRT and other components cannot be rigidly controlled, but good resolution is an absolute necessity. A seven-inch CRT or larger is required to give proper detail, and range increments should be such that only 15 to 100 mi range is portrayed, with the bloom at the center of the scope caused by ground clutter removed by a short range STC or other suitable suppression circuits. The antenna should scan at constant speed of from two to four revolutions per minute since rotation speed determines the number of times a target is illuminated during a given time interval and this affects the echo density on the film. Calibrated dials are necessary on all equipment.

(d) Photographic: A good part of two years was spent in testing and experimentation with various papers and films for use in the integration process. Films proved far superior to papers tested both in ease of evaluation and dimensional stability during processing, minimizing the problem of fitting them with overlays of the rain-gage network for evaluation. Kodak's Transmission Type A (Tran. A) and Fine Grain Positive (FGP) films proved more useful than many others tested. Both have wide latitude of exposure and development, but FGP has a greater variation in available density than Tran. A. Under the exposure conditions used, including a radar receiver having only average dynamic range, either film accomplished the desired result. However, when receivers with greater dynamic range and scopes capable of portraying this entire range as variations in light intensity become available, it may be necessary to use the FGP film having the greatest possible range of available densities for recording precipitation echoes over extended periods of time. Although only limited work has been done with the new Polaroid Projection Type 46L film, it may fulfill most of the requirements for an economical and convenient photo integration material.

It can be shown that the film requirements for constant exposure integration are far more critical than for instantaneous or single sweep CRT photography. In addition, the film should be orthochromatic so that it can be developed easily under safe-light conditions by relatively inexperienced personnel in the field so as to make the data almost immediately available to the hydrologist.

(e) Raingage network: In order to calibrate a given radar for rainfall integration, an efficient raingage network composed of accurate and well-tended gages is necessary. In order to make the best use of a limited number of gages, it is logical that these should be placed in the quadrant which is most vulnerable to destructive floods. Placing them in this fashion will increase the chances of obtaining one or more key gage records to use in evaluating the radarscope photo integration of a flood potential rain.

Conclusions—Although this problem has been studied using an inadequate, but above average, radar, methods have been devised which can be used with other radars to integrate rainfall photographically by operational field personnel. Many of the present radar parameters are capable of improvement in future radars to make them far more useful both for the integration process as well as for general meteorological purposes. Either the point or areal method of analysis can be used to establish the relationship between recorded rainfall and integrated precipitation for a given radar, but the areal method appears more promising for general operational use of the photo integration process.

Acknowledgments—The research leading to this paper was conducted under sponsorship of the Hydrologic Services Division, U. S. Weather Bureau. The authors wish to acknowledge the assistance of W. L. Freseman, who supervised the modification and maintenance of the radar equipment and offered many helpful suggestions for conducting the research. F. H. Stephens assisted by designing equipment modifications; C. L. LaRue and P. E. Norman maintained the equipment and aided in data collection, and C. M. LaPorte assisted in data processing. The research could not have been successfully conducted without the cooperation of the U. S. Navy, Bureau of Aeronautics, and Bureau of Ships in supplying electronic equipment to the University for use on this and other projects.

The Growth of the Atmospheric Internal Boundary Layer

WILLIAM P. ELLIOTT

Abstract—When air, whose wind profile is in equilibrium with an underlying surface, passes to another surface with different roughness, a layer is formed in which the air has adjusted to the new surface. Generally this layer will grow in depth downwind. Assuming the logarithmic wind-speed distribution and Karman's integral equation the height of this layer is computed theoretically as a function of distance. A dimensional argument is also presented which qualitatively confirms the result that the boundary layer grows as the $\frac{4}{5}$ power of the distance downwind and is independent of wind speed. The effect of thermal stability is estimated and found to be relatively small, raising the height of the layer in lapse conditions and lowering it in inversions. Some data are discussed which qualitatively confirm those results but which cannot be considered to be conclusive.

Introduction—In the study of fluid flows a boundary layer is the region in which the effects of the boundaries on the flow are felt. The effect of the boundary is exhibited in a number of ways, the usual ones discussed being transitions from straight flow with no velocity shear to laminar flow or turbulent flow with their respective shears. In this work we shall concern ourselves with the transition from one state of fully developed turbulent flow to another state.

Fully developed turbulence in the region of a rough surface exhibits certain statistical properties which depend, among other things, upon surface roughness and thermal properties. In general, if wind has been blowing steadily over a region of statistically homogeneous roughness for some time, the profile of mean velocity will be in equilibrium with the underlying surface. Assuming the upper-level wind does not change with distance or time, the profile will be the same over the whole area. If, however, this air should pass over another area of different surface roughness or different thermal properties a new equilibrium profile will result. It is reasonable to assume (and in fact observable) that the flow does not immediately adjust at all levels to this new surface but rather the adjustment takes place gradually, the depth of the new equilibrium layer increasing with distance downwind from point of discontinuity in roughness. The transition from the original wind profile will be assumed to take place in a zone of very small vertical extent. This zone will actually be considered as a surface dividing the lower atmosphere into two distinct layers.

The lower layer will be called the internal boundary layer, and the computation of the height of this layer, as a function of distance from the point of transition, is the problem undertaken here.

List of symbols—The following symbols are used.

a	coefficient in power-law formula for boundary layer
a_*	virtual coefficient in power-law formula for boundary layer
c	square root of m
h	height of boundary layer
k	Karman's constant
m	ratio of z_0 below boundary layer to z_0 outside boundary layer
n	exponent in power-law formula for boundary layer
Ri	Richardson number
S	non-dimensional stability factor
u	mean wind speed in x direction
u_h	mean wind speed at top of boundary layer
u_*	friction velocity
x	horizontal coordinate, positive downwind
X	x/z_0
z	vertical coordinate, positive upward from surface
z_0	roughness parameter
$z_0{}^*$	virtual roughness parameter
Z	z/z_0
Z_1	h/z_0
ν	kinematic viscosity
ρ	air density
τ_h	shear stress at height h
τ_0	shear stress at surface

primed quantities refer to values outside boundary layer umprimed quantities to values in boundary layer or general case.

Modified Karman integral theorem—In order to arrive at an analytic expression for the height of the internal boundary layer, we will first make use of a slightly modified form of the Karman integral equation [*Lamb*, 1932, pp. 685–686]. Karman then shows that the total horizontal flux of momentum out of a region bounded by the top of the boundary layer, the surface and two vertical lines a distance δx apart is

Loss of momentum
by advection

$$= \left\{ d/dx \int_{z_0}^{h} \rho u^2 \, dz - u_h \, d/dx \int_{z_0}^{h} \rho u \, dz \right\} \delta x$$

Assuming conservation of momentum (steady state and no body forces) in the boundary layer, this expression must also equal the net gain of momentum due to vertical flux into the region. The gain by vertical momentum flux is simply the difference in the shearing stress between the top and bottom of the column of air considered. Thus

$$\frac{d}{dx} \int_{z_0}^{h} \qquad - u_h \frac{d}{dx} \int_{z_0}^{h} \rho u \, dz = \tau_h - \tau_0 \qquad (1)$$

Both stresses are positive if in the direction of x. In order to use this relation for the evaluation of h, an expression for the variation of u with height must first be chosen.

In order to approximate most closely the actual atmospheric conditions usually observed we will make use of the logarithmic wind profile

$$u = u_*/k \ln z/z_0 \qquad (2)$$

In this relation k is assumed equal to 0.4; u_* is defined as

$$u_* = (\tau_0/\rho)^{1/2} \qquad (3)$$

Changes in z_0 will be assumed to represent changes in surface characteristics in this study. Strictly speaking (2) is applicable only in adiabatic conditions and an attempt to correct the final results for nonadiabatic conditions will be made later.

Internal boundary layer for adiabatic conditions—Figure 1 is a schematic diagram of the internal boundary layer. Assume that the following equations describe the flow

$$u' = u_*'/k \ln z/z_0' \qquad (4)$$

$$u = u_*/k \ln z/z_0 \qquad (5)$$

where the primed quantities in (4) refer to the conditions upwind from the edge and outside the boundary, and (5) describes the flow in the boundary layer. The quantity u_* is assumed to be a function of x but not of z. This is tantamount to saying that the stress in the boundary layer changes with x but at any location it is constant throughout the layer up to $z = h$.

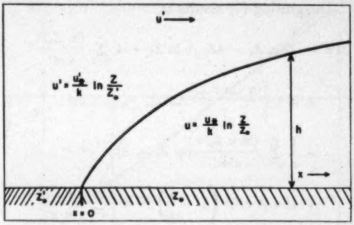

FIG. 1 – Schematic diagram of internal boundary layer

Also assume that at $z = h$, $u' = u_h$. This insures continuity of wind at the top of the boundary layer but further implies a discontinuity in stress. This latter assumption is of course physically unrealistic but comes from the assumption that the change from one regime to another takes place abruptly. In reality, there is probably a transition zone where neither (4) nor (5) is an accurate description of the flow. However, if the transition zone is narrow enough, this need not be considered. Observations seem to support the reasonableness of this assumption.

The assumption of constant stress in the two regions implies that the flux of momentum into the boundary layer from above is $\rho u_*'^2$ and the amount subtracted at the ground is ρu_*^2. Hence (1) can be written

$$\frac{d}{dx} \int_{z_0}^{h} u^2 \, dz - u_h \frac{d}{dx} \int_{z_0}^{h} u \, dz = u_*'^2 - u_*^2 \qquad (6)$$

provided there is no pressure gradient in the x direction.

The solution of (6) will be only indicated here; the full development is given by *Elliott* [1958].

Making these changes in notation $Z = z/z_0$, $Z' = z/z_0'$, $Z_1 = h/z_0$, $X = x/z_0$, and $m = z_0/z_0'$, substituting from (4) and (5), and making use of the assumed continuity of velocity at $z = h$, we arrive at the following differential equation

$$\left\{ \ln Z_1 - 3 - \frac{1}{Z_1} + \frac{4}{\ln Z_1}\left(1 - \frac{1}{Z_1}\right) \right\} \frac{dZ_1}{dx} = \left(1 + \frac{\ln Z_1}{\ln mZ_1}\right) \frac{k^2}{z_0} \qquad (7)$$

Integrating (7) results in

$$\begin{aligned} 2kX = {} & Z_1 \ln Z_1 - 4Z_1 - \ln Z_1 + 4 \sum_{n=1}^{\infty} \frac{(\ln Z_1)^n}{n \cdot n!} \\ & + \ln c \left\{ \frac{\ln (\ln c\, Z_1)}{c} (\ln Z_1 - 3 - 2c) \right. \\ & \left. + \frac{1}{c} \sum_{n=1}^{\infty} \frac{(\ln c\, Z_1)^n}{n \cdot n!} (\ln Z_1 - 3) \right\} \\ & + 4(\ln \ln cZ_1) \left(1 - \frac{1}{c}\right) + 4 \left\{ \sum_{n=1}^{\infty} \frac{(\ln Z_1)^n}{n \cdot n!} \right. \\ & \left. - \frac{1}{c} \sum_{n=1}^{\infty} \frac{(\ln c\, Z_1)^n}{n \cdot n!} \right\} + \text{constant} \end{aligned} \quad (8)$$

where the constant of integration will depend upon values of c as determined by the condition that $h = z_0$ at $x = 0$.

The boundary conditions present certain difficulties. The most convenient assumption to be made, that the boundary layer begins to grow at $x = 0$, may not be true in actual practice. Also, near the origin where the boundary has not attained an appreciable height, the assumptions of constant stress and the logarithmic profile may not be strictly accurate. Consequently, not much reliance should be placed on the solutions in the very lowest layers (say $z = 10$ cm, $x = 100$ cm).

Eq. (8) gives X explicitly as a function of Z_1 with m as a parameter, or Z_1 implicitly as a function of X and m. Sufficient numerical work was carried out to define the curves for Z_1 versus X over a wide range of these variables for the following values of m: 0.01, 0.05, 0.1, 0.2, and 0.5($z_0 < z_0'$); 1 (no change of surface condition); and 2, 5, 10, 50, 100 ($z_0 > z_0'$). Figure 2 shows the plots of three of the curves which were obtained from the computations.

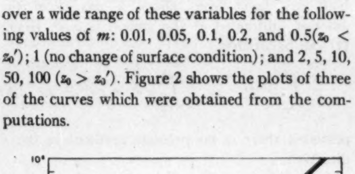

FIG. 2 – Growth of internal boundary layer with distance

The formal solution is extremely clumsy, and the general shape of the family of curves for m in the Z_1X plane is not apparent from the equation itself. Actually, it was somewhat surprising when the graphs of (8) showed such a smooth appearance. It is apparent from the curves in Figure 2 that the functional relationship can be approximated by the simple formula

$$Z_1 = aX^n \quad (9)$$

for $X > 10^3$. The latter condition implies that x should be of the order of ten meters or greater for typical ground surfaces. The slope of the straight portion of the curves in Figure 2 leads to a value for m of 0.80; the corresponding value for a is 0.75 for the case of $m = 1$. It was found that the value of n could be taken constant regardless of m, and for the range of m considered the coefficient a varies from 0.6 to 0.9 approximately according to the relation

$$a = 0.75 - 0.03 \ln m \quad (10)$$

It is seen from this result that the height of the boundary layer (for a given position x) will be greater for air flowing from a rough surface to a surface of less roughness ($z_0 < z_0'$) than for the opposite situation. However, even if z_0 differs by a factor of 100 from z_0', the height is changed by only 20 pct relative to the case of $m = 1$. Comparison of the above results with observations is presented in a later section.

Dimensional argument—A result of the previous section which was not intuitively obvious was that (8) does not contain the wind speed or u_*. In other studies of boundary layers the height is dependent upon some power of the wind speed or free stream velocity. In the transition from straight to laminar flow over a smooth plate the height is proportional to the square root of the free stream velocity and for laminar to turbulent flow the height is proportional to the one-fifth power of the free stream velocity [see *Schlichting*, 1955].

The turbulent flow discussed here is physically distinct from the case we have been considering in the previous section. In the case of turbulent flow over a hydrodynamically smooth surface viscosity is an influencing factor, whereas, in the case under consideration, flow over a hydrodynamically rough surface, the surface characteristics play a more dominant role than viscosity. In the case of a smooth surface, a thin laminar sublayer occurs close to the surface while for a rough surface the turbulence extends to the surface. In fact, in the case of a smooth surface, previous investigations [*Schlichting*, 1955] indicate

$$u_h h/\nu \propto u_h x^{0.8}/\nu \tag{11}$$

Experimental evidence also indicates that the velocity profile

$$u/u_* \propto \ln (u_* z/\nu) \tag{12}$$

in the case of turbulent flow over a smooth plate and

$$u/u_* \propto \ln z/z_0 \tag{13}$$

in the case of turbulent flow over a rough plate. In the latter case viscosity is no longer important, and z_0, a measure of the surface characteristics, appears. Furthermore it appears that the term $u_* z_0$ has replaced ν in (12) as the relevant parameter for determining the velocity profile. If it is permissible to extend these empirical results for the profile to the boundary layer situation then the replacement of ν by $u_* z_0$ in (11) leads to

$$(u_h/u_*)(h/z_0) \propto (u_h/u_*)^{4/5} X^{0.8} \tag{14}$$

However

$$u_h/u_* \propto \ln h/z_0 \tag{15}$$

by (13). So finally we have, substituting (15) in (14),

$$(h/z_0)(\ln h/z_0)^{1/5} \propto X^{0.8} \tag{16}$$

Thus this argument has resulted in the elimination of the wind speed and u_* as well as the viscosity, which is in agreement with our previous results.

The term $(\ln h/z_0)^{0.2}$ which appears in (16) is virtually constant over a large range of h/z_0, varying from 1.47 at $h/z_0 = 10^3$ to 1.79 at $h/z_0 = 10^8$. Consequently (16) will not be radically different from the approximate form (9). Figure 3 shows a comparison of (8) for $m = 1$, (9) with $a = 0.75$ and $n = 0.8$, and (16) fitted to (8) at $h/z_0 = 10^3$. One can see that (16) can be made a better approximation to (8) than (9).

Effect of stability—It now remains to estimate the effect which atmospheric stability might have on the height of the internal boundary layer. Ideally we would like to be able to substitute some form for the nonadiabatic profile in (1) and integrate as was done with the adiabatic profile (2). However, the equations available to describe the non-adiabatic profile all proved intractable. Consequently, a method by which the effect of stability could be estimated was devised. This method is not accurate but it serves to indicate the general effect.

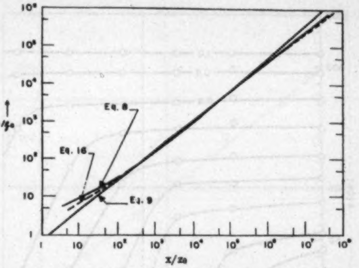

FIG. 3 – Comparison of Equations (8), (9), and (16)

In a review of some of the descriptions of non-adiabatic profiles, *Elliott* [1957] concluded that there is little to choose between those he compared. He suggested a form

$$u = u_* \ln Z(1 - SRi_0)/(1 - SRi) \tag{17}$$

where $S = 3.5$ (the subscript 0 refers to the Richardson number at height z_0). If this expression is substituted in (1) the fact that Ri is a function of height precludes integration. However, if we define an effective z_0 as

$$z_0^* = z_0(1 - SRi)/(1 - SRi_0) \tag{18}$$

we can use this z_0^* in the equation for the boundary layer height. In (9) we can replace a by $a^* = a(z_0^*/z_0)^{1-n}$. In cases of instability where the Richardson number is negative the result would be $a^* > a$, and hence a higher boundary layer than in the adiabatic case. The opposite would be indicated for stable conditions.

Consider the case where the term SRi_0 is essentially zero and a representative value of $-SRi = 0.7$ (corresponding to $Ri = -0.2$). The value of z_0^* is then 1.7 z_0 which gives $a^* = 1.1a$, indicating only about a ten per cent increase in the value of h.

We will then tentatively conclude that instability leads to a small fractional increase in the height of the boundary layer and that stability leads to a small fractional decrease in the height of the boundary layer, relative to the adiabatic case.

Observations—We should now focus our attention on several observations of boundary-layer heights which have been obtained. Data on the growth of this boundary layer in the atmosphere are indeed scarce. *Glaser* [1955b] obtained wind

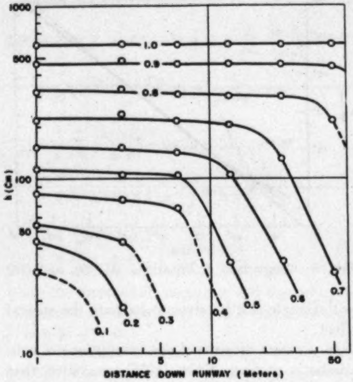

FIG. 4 – Relative wind cross-section [from *Glaser*, 1955b]

profiles along a runway in connection with a study of the temperature structure over a runway on a hot day. We will first briefly describe the equipment used in his study.

A vertical mast was constructed which held eight pairs of anemometers and thermistors, spaced roughly logarithmically with height. The highest pair was approximately six meters above the surface and the lowest pair about ten centimeters above the surface. The anemometers were small three-cup Robinson type, imported from Japan. The instruments were arranged in such fashion that their readings could be recorded in the interior of a converted laundry van. This van towed the entire apparatus so that measurements could be taken at different places with a minimum amount of time lag. Details of the apparatus can be found in reports by *Glaser* [1955a] and *Glaser* and *Elliott* [1956].

The observing site was the Naval Air Station at Houma, Louisiana, which was relatively inactive. The area surrounding the runways was covered with grass about one meter high. The general plan was to await such time as the wind was blowing down the runway. The temperature and wind profiles were first measured at the upwind edge of the runway and at various locations, spaced approximately logarithmically, down the runway. The winds and temperatures reported were averages over five minutes of continuous observation.

From the observed wind speeds it was possible to construct isopleths of wind speed in the xz plane. A segment of this graph for the observation period, August 17, 1955 14h 06m–15h 22mCST, taken from the original work of Glaser, is presented in Figure 4. The isopleths shown are those of the wind speed relative to the six-meter wind. It can be seen that the relative wind-speed isopleths indicate a sharp change in wind speed at different points in the xz plane. The ispoleths can be approximated by two intersecting straight lines except in the region of maximum curvature. The intersection of these lines was taken as the height of the boundary layer, conforming to the original definition. The results of this particular observation period are shown because they present the most clear-cut case of an internal boundary layer. Because of the relative narrowness of runways, slight shifts in wind direction would bring air from the sides across the runways which gives rise to confusion in determining the boundary layer. However, several other observations showed this boundary layer and the same general shape was indicated [see *Glaser*, 1955b].

Figure 5 shows the height of the boundary layer (encircled points) as derived in the above manner. The straight line is the graph of

$$h = 0.86\, x^{0.8} z_0^{0.2}$$

where z_0 has the value 0.02 cm.

It appears that the value of 0.8 for the exponent is in excellent agreement with the observations. The value of z_0 (0.02 cm), obtained from observations of wind profiles over the runway, is quite representative of concrete surfaces. Since z_0 appears to the 0.2 power the final result will not be very sensitive to small errors in z_0. The value of the coefficient is more open to question. The surrounding grass was quite high and the value of z_0 for the grass is somewhat in doubt, but is estimated to be of the order of two or three centimeters. For these reasons only an approximate value of z_0/z_0' can be made. The value of $a = 0.86$, chosen because it best fits the data, falls within the theoretical range of 0.6–0.9. Thus, it appears that the value of 0.8 for the exponent is well verified, while the value for the coefficient is at least in the proper range.

Since these observations were taken on a hot, clear day the temperature gradient was definitely nonadiabatic. However, the value of the exponent remains the same (0.8). Because of the difficulty of obtaining the proper value of z_0/z_0' it is difficult to estimate the true effect of this term. Nevertheless, this result tends to confirm our conclusion regarding the effect of stability, namely, that it is small and that the boundary layer is higher in lapse conditions than it would be in neutral conditions.

Interpretation in terms of smoke plumes—Two other independent observations in this regard seem worth considering. As was mentioned earlier, the original equation was integrated for $m = 1$; that is, no change in z_0. At first glance, this seems to be a fairly meaningless solution since no boundary layer should exist if there is no change in z_0. However, a possible interpretation may be found in considering that the value of h defines the zone of influence of each blade of grass or obstruction to the flow. If each obstruction has the same effect as its neighbor, then no change in the actual flow will occur. But if the obstructions vary in the x direction, then we would expect to find the effect of this variation in roughness reflected in the actual wind field. It appears possible that in the case of no change in z_0 the height of the boundary layer might be shown by the downwind height of a smoke cloud introduced at $x = 0$. If this hypothesis is correct, then observations of the height of a smoke cloud could give values of the height of the boundary layer and also indicate some effects of thermal stratification.

Sutton [1953] reported average data for diffusion from a steady continuous source in small temperature gradients. The only figure cited for the height of a smoke cloud was ten meters at 100 m distance from the source. No value of z_0 was cited, but since the observations were taken over level downland, the value of z_0 probably lies in the range 0.2 to 0.8 cm. Using the formula

$$h = 0.75\, x^{0.8} z_0^{0.2} \tag{19}$$

gives a range of h of 8.6 to 11.3 m, which can be considered very good (a value of z_0 slightly less than 0.5 cm would give $h = 10$ m).

Sutton also presented a derivation of the height of the smoke cloud and found that the height was independent of wind speed and proportional to $x^{7/9}$. The analytical investigation given here is in excellent agreement with Sutton's findings. Sutton stated that his theoretical results had been verified by measurements for small temperature gradients.

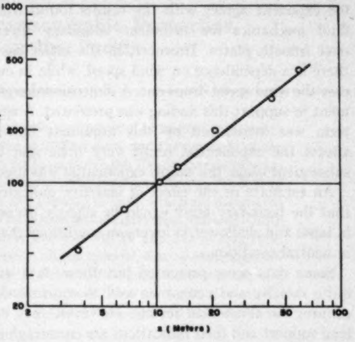

FIG. 5 – Observed and computed growth of internal boundary layer

Another set of diffusion measurements was taken by *Record* and *Cramer* [in press] in connection with the AFCRC Project Prairie Grass. According to them, the plume heights at 100 m from the source averaged 12.5 m in conditions of thermal instability and eight meters in the presence of thermal stability. For the conditions under which these observations were made, the value of z_0 was about 0.7 which would lead to a height of 11 m for average adiabatic conditions. This is again in good agreement with the observations and seems to confirm the hypothesis that instability increases the height of the boundary layer while stability decreases it.

Thermal internal boundary layer—It should also be pointed out here that an analysis similar to the above can be performed for the adjustment of the temperature profile to a new surface temperature in an analogous fashion. This has been performed by *Ogura* [1950] and *Elliott* [1958]. Although their initial assumptions are slightly different, they both arrived at the same equation

$$k^2 x/z_0 = h/z_0 \ln h/z_0 - 3\, h/z_0 + 2 \sum_{n=1}^{\infty} \frac{(\ln h/z_0)^n}{n \cdot n!} + 3 \tag{20}$$

Elliott further showed that this equation could be approximated by

$$h/z_0 = 0.35(x/z_0)^{0.8} \tag{21}$$

which is quite similar to our results for the momentum internal boundary layer. In the Ogura paper one observation is presented which confirms the result in at least one point.

Summary and conclusions—To recapitulate, an expression for the growth of the internal boundary layer has been derived for an adiabatic lapse rate. The resulting expression was approximated by a power-law equation whose exponent is 0.8. This

0.8 exponent agrees with the results found from fluid mechanics for turbulent boundary layers over smooth plates. However, in the latter case, there is a dependence on wind speed, while in our case the wind speed drops out. A dimensional argument to support this finding was presented. A new term was introduced by this argument but it affects the exponential result very little and in subsequent usage the simple exponential was used.

An estimate of the effect of stability indicated that the boundary layer would be slightly deeper in lapse and shallower in inversion conditions than in neutral conditions.

Some data were presented but these data are quite sketchy and cannot be said to conclusively confirm the theoretical results. However, they do lend support and their indications are encouraging.

The need for further observations of the type made by Glaser must surely be apparent. Such measurements made normal to a long discontinuity line would alleviate some of the difficulties encountered along a narrow runway. Perhaps a shoreline or an agricultural field would be adequate.

There is no reason to suppose that such a boundary layer would not be present in the vapor pressure field as well. Under these boundaries the fluxes of momentum and heat change quite radically near the upwind edge and presumably the vapor flux would exhibit similar changes. The presence of the internal boundary layer may contribute to the discrepancies between evaporation pan measurements and the actual evaporation. These considerations are discussed in more detail by *Glaser*, *Elliott* and *Druce* [1957].

Acknowledgments—The author would like to express his gratitude for the assistance and guidance given by Robert O. Reid and Arnold Glaser then of the Department of Oceanography and Meteorology, A & M College of Texas. Oscar Chancey and Mrs. William Howell of the Department of Oceanography helped considerably with the computations and the drafting of the figures, and Helen Scott typed the manuscript.

Some of the work reported above was sponsored under Air Force Contract AF19(604)-997. Part of this paper formed a section of the author's Ph.D. dissertation at A & M College of Texas. This is Contribution No. 125, Oceanography and Meteorology Series, Department of Oceanography and Meteorology of the Agricultural and Mechanical College of Texas.

Variations with Depth of Oceanographic Properties Along the Equator in the Pacific

THOMAS S. AUSTIN

Abstract—The vertical distribution along the equator in the Pacific of temperature, salinity, density, oxygen, and phosphate, from the sea surface to 1000 meters, and the anomaly of the dynamic height of the sea surface and other isobaric surfaces above the 700-decibar surface are shown. In each of the figures, the available data have been partitioned according to the date of the observation into two periods, July to December and January to June, which are designated in the text as summer and winter, respectively. The figures include data from stations within one degree of latitude north or south of the equator between 110°W and 135°E longitude.

The surface of the sea, relative to the 700-db surface, slopes upward, east to west, approximately 0.8 dynamic meters; the value for the slope is 5.0×10^{-8} during both summer and winter. The longitudinal pressure gradient does not extend much below the layer of relatively large vertical density gradient. At the depth of $\sigma_t = 26.5$, 250–300 m, relatively little east-west slope is evident.

In the surface layer (sea surface to top of the thermocline), temperatures along the equator are lower in the eastern Pacific during both periods; the thermocline is comparatively level west of the 180th meridian, sloping upward to the east of this longitude. Temperatures are appreciably lower and concentrations of inorganic phosphate are higher in the surface layer in the eastern Pacific during the summer, both reflecting the temporal and longitudinal variations in divergence and upwelling.

The oxygen minimum, centered at a depth of approximately 450 m, is a continuous feature from 100°W longitude (eastern limit of the profiles) to near 170°E longitude, with the lowest concentrations in the east (≤ 0.5 ml/L) increasing to 1.5 to 2.0 at the westward limit. West of 170°E longitude, concentrations at 450 m rapidly increase to 3.0 ml/L.

In recent years, numerous profiles illustrating the vertical distribution of properties along meridional (north-south) sections crossing the equator in the Pacific have appeared in the literature. Data thus presented included, for examples, those from cruises of the *Carnegie* [*Sverdrup* and others, 1942], the *Hugh M. Smith* [*Austin*, 1954a; *Montgomery*, 1954; and *King* and others, 1957], the *Albatross* [*Jerlov*, 1956], and various Japanese research vessels [*Mao* and *Yoshida*, 1955]. These data, which were rather widely spaced with respect to both geography and time, were inadequate for consideration of seasonal variations in trans-Pacific vertical profiles, particularly along the equator.

During August through October 1956, 12 vessels participated in EQUAPAC, a quasi-synoptic oceanographic survey of the equatorial Pacific between approximately 20°N and 10°S latitude and 135°W to 135°E longitude. Data from EQUAPAC, plus those from previous and subsequent surveys, now make it possible to study in some detail the vertical distribution and seasonal variations of properties along the equator. In the accompanying figures, profiles for temperature, salinity, density (σ_t), oxygen, and inorganic phosphate, and the anomaly of the dynamic height of the sea surface and other isobaric surfaces above the 700-db surface are shown.

The stations selected for use in the figures were all located within one degree of latitude (60 nautical miles) north or south of the equator. Pertinent information for the stations, each of which has been designated by a letter-number combination on the figures, is listed in Table 1. Wherever available, interpolated data from each station were plotted at standard depths, otherwise observed data were used. In drawing the contours, an effort was made to suppress configurations which apparently resulted from station-to-station temporal variations. This was not always possible without violating plotted values and consequently localized irregularities appear in the isopleths. Some available data were not utilized because they appear to have been recorded during seasons or years which were atypical for their longitude. For example, at *Carnegie* Station 98 near 175°W, the temperatures from the surface to depths somewhat below the thermocline were considerably higher (+6° to +10°C at 200 m) than those for nearby stations, resulting in a pronounced trough in the isotherms.

There are two profiles for each of the fields depicted, one for the period July to December, the other for January to June. These two periods, for simplicity of terminology and discussion in the subsequent text, have been designated as 'summer' and 'winter,' respectively, without implication as to the summer and winter seasons recognized in higher latitudes. The division of the year into the two six-month periods resulted primarily from consideration of the seasonal variability in the trade winds and also from the necessity of selecting periods within which there would be a sufficient number of stations to provide adequate data for the sections. The southeast trades (of particular significance along the equator) are at maximum constancy and force in August–September, minimum in March–April.

Vertical profiles along the equator are of diversified interest. As expressed by *Montgomery* and *Palmén* [1940], the equator is the ideal location for determining the longitudinal pressure gradient. At the equator there can be no cross-stream gradient because deflecting force and compensating pressure gradient both vanish. Of interest to both the physical oceanographer and the marine biologist are the east-west (and seasonal) variations in the

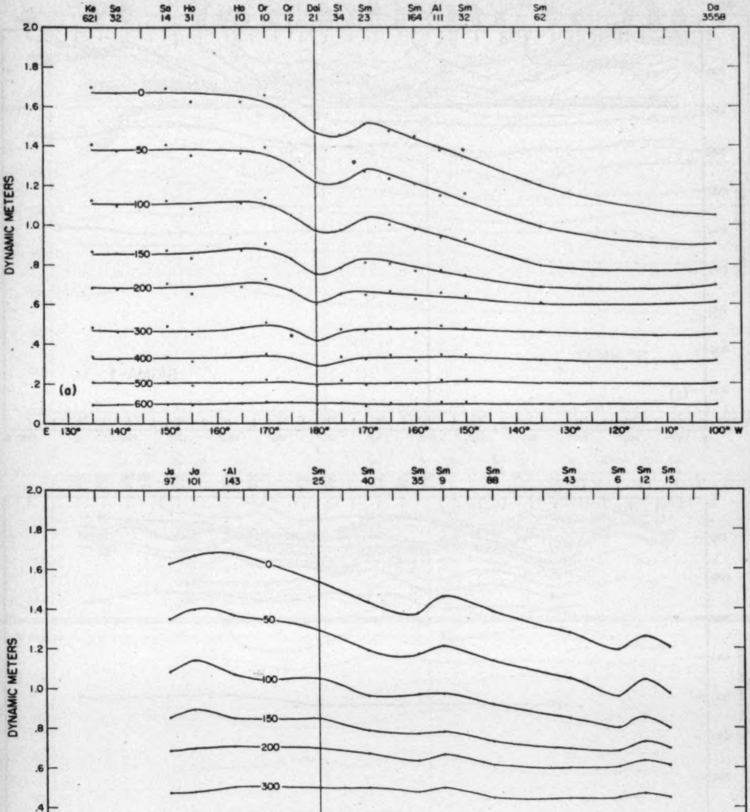

FIG. 1 – Anomaly of the dynamic height of the sea surface and other isobaric surfaces above the 700-db level; (a) July to December; (b) January to June; see Table 1 for position, date, and source of data for each station designated along the top borders

slope of the thermocline and of the equatorial divergence and upwelling.

In Figure 1 we have shown the anomaly of the dynamic heights for the sea surface and other isobaric surfaces, all relative to the 700-db assumed level of no motion. During both periods, the sea surface slopes upward, east to west, with a mean value for the slope of 5.0×10^{-8} (0.8 m in 15×10^3 km) during both the summer and the winter. ***Montgomery*** and ***Palmén*** [1940] calculated the slope to be 4.5×10^{-8}.

Between the two periods there are variations in

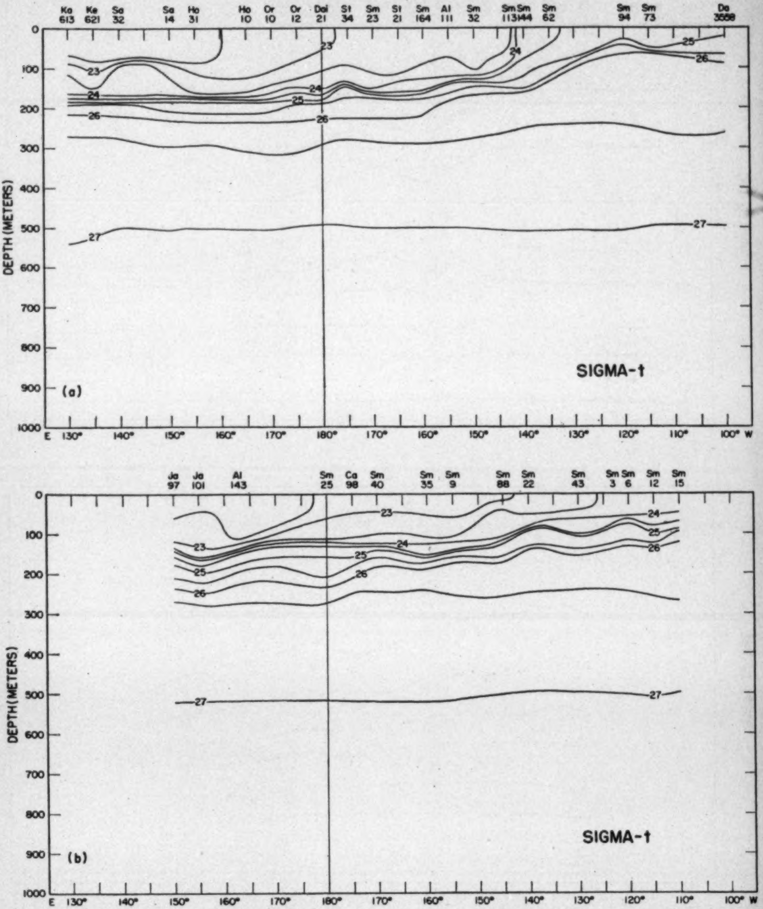

FIG. 2 – Density; contour interval 0.5 units of sigma-*t*; (a) July to December; (b) January to June

the height of the sea surface in the eastern Pacific. During the summer, east of approximately 165°W longitude, the surface is 10–15 dynamic centimeters lower (relative to the 700-db surface) than during the winter. The dips in the anomaly of the dynamic height of the sea surface near 180° in the summer and 165°W in the winter are difficult to explain. Enough stations are involved in each case to suggest that they are a real feature.

Montgomery and *Palmén* [1940, Fig. 43] demonstrate that the longitudinal pressure gradients in the Atlantic and the Pacific do not extend below the layer of relatively large vertical gradient in density (hereinafter referred to as the stable layer).

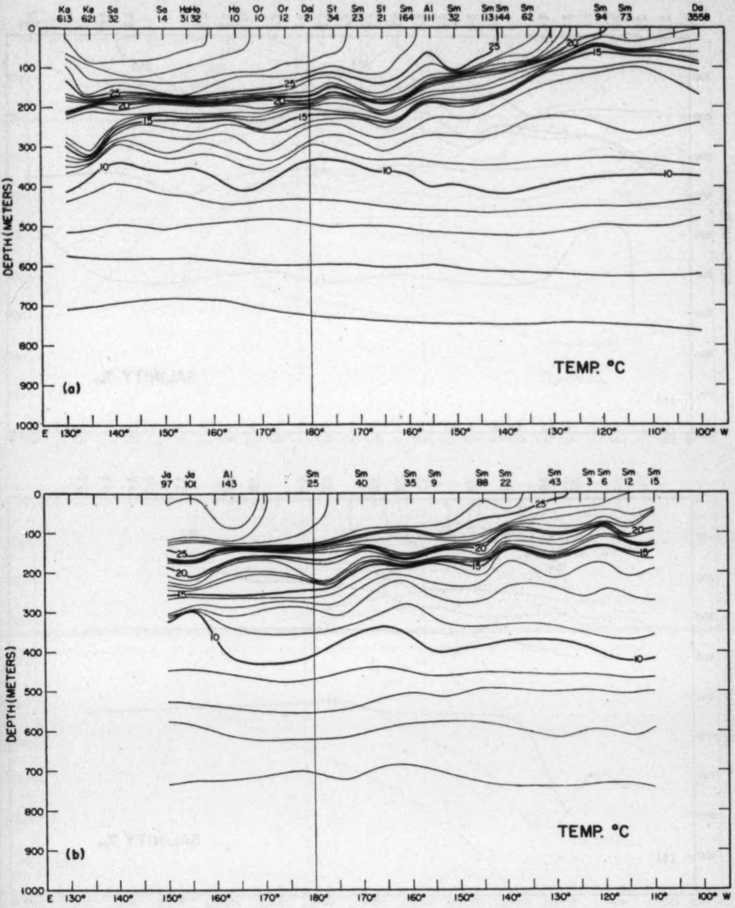

FIG. 3 – Temperature; contour interval 1°C; (a) July to December; (b) January to June

For their analyses of the situation in the Pacific, data for only two positions were available, one at 99°07′W, the other at 134°44′E longitude. Using the data from the stations included in Figure 1, the σ_t distribution along the equator is shown in Figure 2. Although, when comparing Figures 2a and 2b, variations in density are evident in the surface layer (surface of the sea to top of the stable layer) and in the east-west slope of the stable layer, the 26.5 isopleth (250–300 m) in both figures shows relatively little east-west slope.

During the summer, the east-west slope of the stable layer is steeper than in the winter east of 160°W; conversely to the west of 160°W, the slope

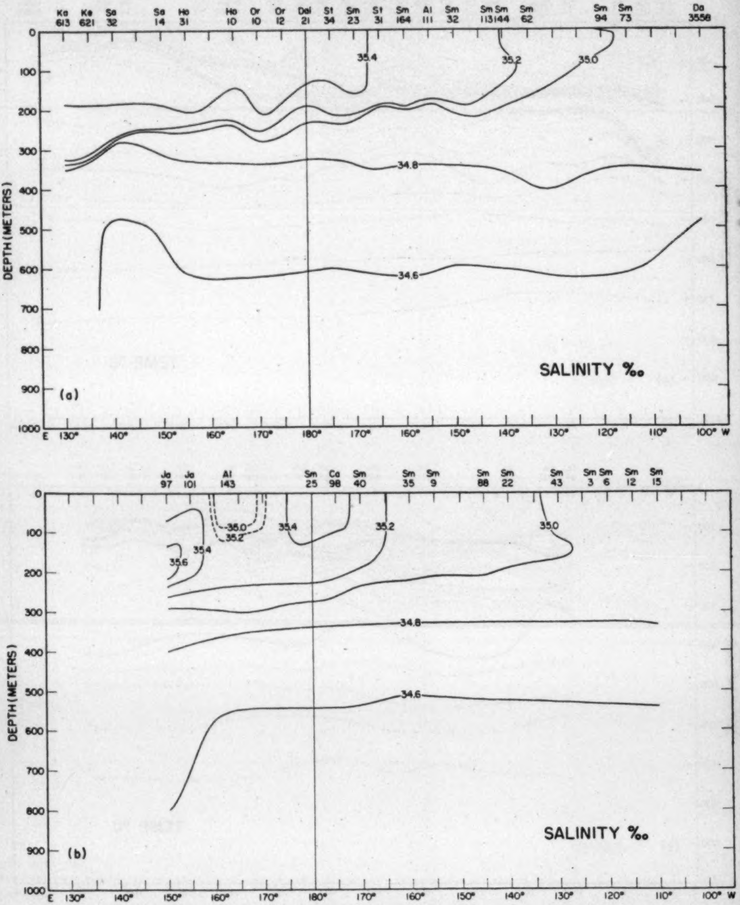

FIG. 4 – Salinity; contour interval 0.2 per mille; (a) July to December; (b) January to June

is less in summer than in winter. In terms of depth of the stable layer, in the west it is deeper and in the east shallower in summer than in winter. These variations, evident in Figure 2 (and 3), reflect the greater volume of lighter, warmer water in the western Pacific during the July to December period.

Variations in density and thus in the results of the geostrophic calculations in the tropical Pacific are principally a function of variations in temperature. The vertical distribution of temperature is shown in Figure 3. In general, the temperatures in the surface layer are cooler in the eastern Pacific than in the west; the thermocline is comparatively

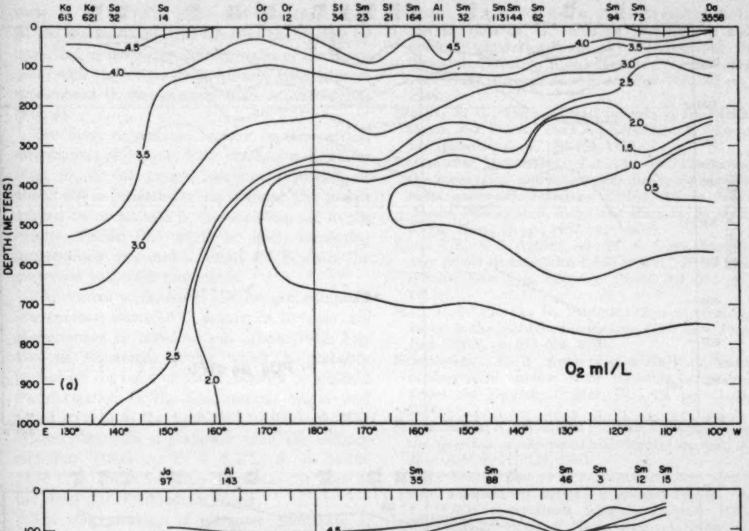

FIG. 5 – Oxygen; contour interval 0.5 milliliters per liter; (a) July to December; (b) January to June

level in the western Pacific, sloping upward east of the 180th meridian [*Sverdrup* and others, 1942, Fig. 197]. During the summer period, particularly in the eastern Pacific, the temperatures of the surface layer are considerably cooler than during the winter, while in the west, summer temperatures are warmer to greater depths.

Austin and *Rinkel* [1957], in part through a comparison of meridional temperature sections, have shown that there is an east-west variation in upwelling at or near the equator in the Pacific with the maximum mixing of the deeper, cooler waters with those at the surface being in the eastern central Pacific. In addition, they state

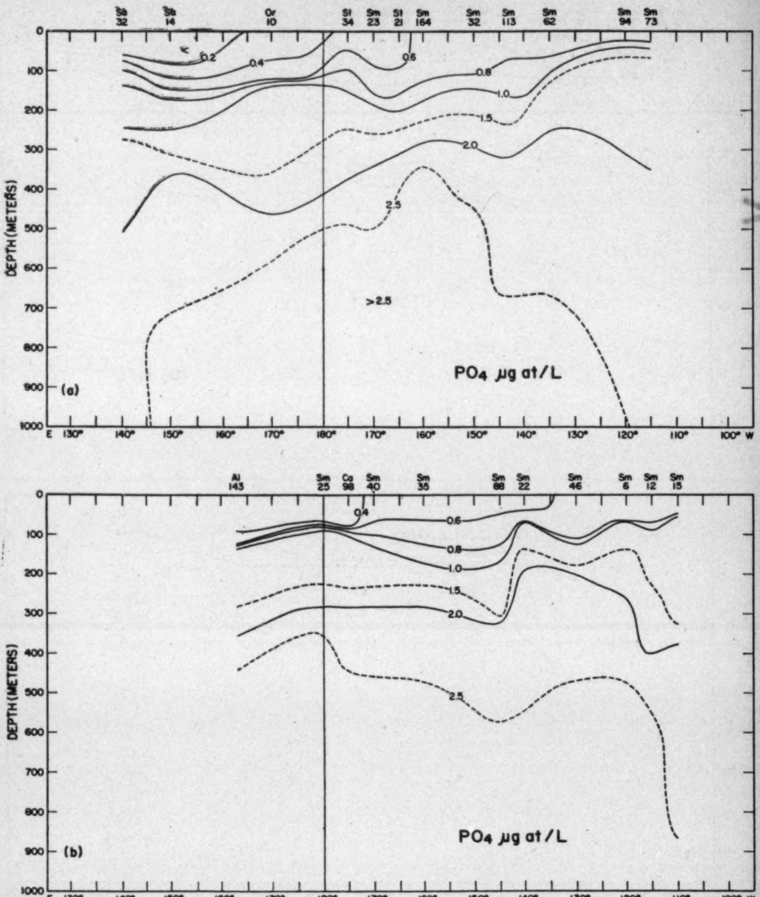

FIG. 6 – Inorganic phosphate; contour interval 0.2 for concentrations less than 1.0 microgram atoms per liter; 0.5 for concentrations greater than 1.0 microgram atoms per liter; (a) July to December; (b) January to June

that the period of most active upwelling is during August through October, the period of the maximum constancy and force of the easterly component of the southeast trade winds. These conclusions are reflected in the cooler surface waters in the eastern portion of Figure 3a.

The more active upwelling in the eastern Pacific during the summer is also reflected in the vertical distribution of salinity (Fig. 4). In the eastern Pacific, the mixing processes associated with upwelling limit the penetration of the waters of the intermediate salinity maximum into the northern hemisphere [*Austin*, 1954b; *Austin* and *Rinkel*, 1957]. In the western Pacific, these waters penetrate to 5° to 10°N [*Mao* and *Yoshida*, 1955]. In the eastern Pacific the effect of the mixing by upwelling of the higher salinity water of the maximum with the waters in the surface layer is more pronounced in the summer than in the winter (Fig. 4).

The most pronounced feature in the vertical distribution of oxygen, both summer and winter (Fig. 5), is the oxygen minimum centered at about 450 m beneath the sea surface. The lowest oxygen concentrations in the minimum are in the eastern Pacific (0.5 ml/L or less), increasing progressively westward to about 165°E where the minimum essentially terminates.

The waters at depths of the oxygen minimum (temperature about 9.0°C, salinity 34.70 $^0/_{00}$) are characterized by *Sverdrup* and others [1942, Fig. 196] as Equatorial Water which is probably formed off the coast of South America by gradual transformation of the Subantarctic Water and which spreads to the north and to the west. The oxygen minimum is shallower than the salinity minimum (1000 m, $T = 5.5°\mathrm{C}$, $S = 34.50$–34.58 $^0/_{00}$) which Sverdrup denotes as the 'core' of the Antarctic Intermediate Water.

The concentrations of inorganic phosphate in the surface waters (Fig. 6) are comparatively higher in the eastern Pacific, 0.6–0.8 μg at/L as compared with $\leq$0.2 μg at/L in the western half of the ocean. In general, east of 160°W they are higher during July to December, the period of most intensive upwelling.

Statistics on Wave Heights and Periods for the North Atlantic Ocean

R. L. BROOKS, N. H. JASPER, AND R. W. JAMES

Abstract—This paper gives the frequency distributions of wave heights and wave periods obtained from weather ships stationed in the North Atlantic, together with an evaluation of the reliability of the visual wave-height estimates comprising the basic data from which the distributions are derived. Visual estimates are compared with values determined from stereophotographs. An additional check is provided by wave-meter measurements. It is shown that a log-normal distribution is applicable to the frequency distribution of wave heights experienced over a typical year and that this distribution is a useful guide to the determination of the incidence of a particular sea state at a given location.

Data from weather ships—Wave heights and periods for ten ocean stations were obtained from U. S. Weather Bureau records. These data are visual estimates covering a period of six years and were made every three hours by trained weather observers. By international agreement, all ocean-station vessels use the same methods of estimating, as described by the *U. S. Weather Bureau* [1950; pp. 57–58]. Only one quantitative value for wave height and one for wave period were reported each time the sea was observed.

Visual estimates for correlation against stereo data—In order to evaluate the accuracy of the visual wave estimates and their usefulness in the statistical analyses, stereocameras were installed on one of the weather ships, the USCGC *Unimak* (WAVP 379), and on the USS *Valley Forge* (CVS 45).

Visual estimates of the sea surface were made by trained observers at the same times that stereophotographs were taken. The *Unimak* estimates were made by regularly assigned Weather Bureau observers. The *Valley Forge* estimates were made by trained Navy aerological personnel; two or more of them made independent estimates twice each hour during most observation periods. By special arrangement, five or six of the Navy aerological personnel made independent wave estimates three times each day. Subsequently, the *Valley Forge* estimates were averaged and plotted against time of observation and a smooth curve was fitted to these points. From these curves, characteristic wave heights were obtained and are entered in Column 7 of Table 1.

The times shown in Columns 3 and 4 of Table 1 are local civil time values for the time zone in which each observation was taken. Each of the ship positions shown in Column 4 of Table 1 was obtained from the vessels' regularly developed navigation data; positions shown are those that were closest in time to each of the observations of wave data.

In making their observations, the Weather Bureau personnel on the *Unimak* followed the instructions of the *U. S. Weather Bureau* [1950], which specifies "larger, well-formed waves." The Navy observers were guided by the *U. S. Hydrographic Office* [1955], which calls for "higher, well-defined waves." It is apparent that the estimating procedures specified by these two different organizations are essentially the same.

Throughout this report the term 'characteristic height' will be used to denote *the average height of the higher, well-defined waves*. The statement italicized will serve as a definition of this quantity. The term 'significant wave height' will be used only in its statistical sense *as the average of the ⅓ highest waves*. The 'characteristic wave period' is *the average period* of the higher well-defined waves.

Data from sea surface profiles—Of the many hundred stereophotograph pairs taken during the sea trials, 60 were selected for analysis to cover as wide a range of sea conditions as practicable. Each of these was converted into sea-surface profiles by photogrammetric specialists at the Naval Photographic Interpretation Center or Navy Hydrographic Office. The Wild A5 Autograph and Zeiss Stereo Planigraph Model C5 were used by the respective agencies, and vertical mapping techniques were adapted to this horizontal application. Next, the sea-surface profiles were analyzed by the Oceanographic Division of the Hydrographic Office. The accuracy of a wave profile varies with the distance from the camera to the profile. The average accuracy is about ±0.5 ft at a distance of 2000 ft and is better than this at shorter distances.

The sea-surface profiles were used to determine the characteristic wave heights by following the same general procedure as that used by the shipboard observers in making their estimates; thus these two independent determinations of characteristic wave height should be comparable. These values are shown in Column 9 of Table 1.

Statistical background—Wave heights and wave periods from the weather-ship data for ten ocean stations are presented in the form of their distribution functions. For example, all wave heights reported by the shipboard observers are considered to be members of a statistical population of wave heights. The distribution function of wave heights indicates the relative probability of encountering a wave of a given height as a function of that height. Figure 1 illustrates this distribution function. The area under the curve to a value x_i is the integral of the function up to x_i and is equal to the fraction of all members of the population of wave heights which have a height less than x_i. Mathematically

$$P(x) = \int_0^x p dx \quad \text{and} \quad P(x \to \infty) = \int_0^\infty p dx = 1$$

where p is the probability density and P is a function of x designated as the cumulative distribution function of x. $P(x)$ is numerically equal to the probability that a value chosen at random from the population is less than x.

A detailed discussion of the statistical methods utilized in this report is given by *Jasper* [1956]. Only a few of the major concepts will be described here. The distribution applicable to a given sea condition is here called a 'short-term' distribution, whereas the distribution applicable when the sea conditions are allowed to vary over a wide range, such as over a year's time, is called a 'long-term' distribution. Thus the long-term distribution is the result of a summation of a number of short-term distributions. Oceanographers have held that the short-term distribution of wave heights x is approximately of the Rayleigh type (a narrow power-spectrum is assumed) for which

$$p(x) = \frac{2x}{E_i} e^{-x^2/E_i}$$

where E_i is the mean square of all the individual wave heights x corresponding to sea condition i. Note that numerically the value of E computed for wave height will be four times the value of E computed for wave amplitude because wave height is taken equal to twice the wave amplitude. See *Pierson* and others [1955] and *St. Denis* and *Pierson* [1953] for a discussion of the distribution of wave heights in terms of the power-spectrum concept. The short-term distribution is approximately valid if measurements are taken over a relatively short period of time, of the order of one hour, during which interval the sea conditions do not change appreciably. It can be shown that this distribution is the same as that representing the wave heights, in the area under consideration, at one instant of time.

Jasper [1956] suggested that the long-term distribution of wave heights and wave periods is of the log-normal type, that is, that the logarithms of these heights and periods are approximated by a normal distribution. Thus

$$p(\log x)d(\log x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(\log x - u)^2/2\sigma^2} d(\log x)$$

$$P(x) = P(\log x) = \int_{\log x = -\infty}^{\log x} p(\log x)d(\log x)$$

where $p(\log x)$ is the probability density of the variate, $\log x$, u is the mean value of $\log x$, and σ^2 is the variance of $\log x$. Then the parameters u and σ define this distribution completely.

In this report log-normal distributions are fitted to the characteristic wave heights and periods reported by the weather ships. The resultant graphs give the probability with which a given value of the variate x will or will not be exceeded in an average year. Although the distributions given here are for a six-year period, study of distributions for individual years making up the six-year period indicates that a single year gives a

[a] *E* is the mean square value of wave heights.

[b] 1954, not 1955.

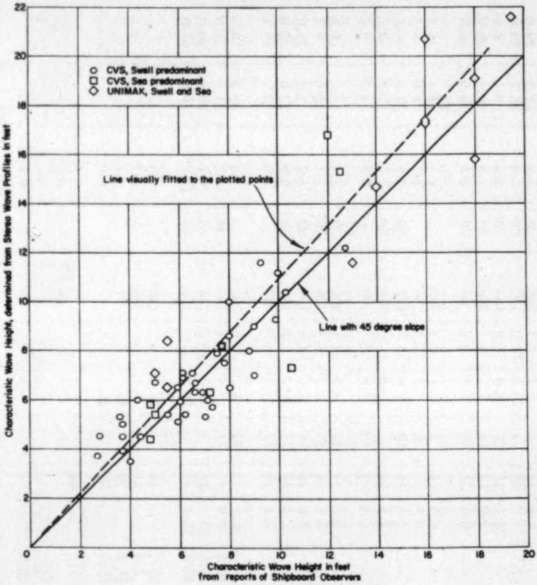

FIG. 2 – Scatter diagram for comparison of characteristic wave heights determined independently from the wave-profile analysis and by shipboard observers; data from Table 1, Columns 7 and 9

typical sample of the distribution obtained for many years. Therefore, the six-year distribution may be considered valid for an average year.

Evaluation of reliability of visual estimates of wave heights—The characteristic wave heights obtained by the shipboard observers are compared with those derived from the stereograms for the same sea condition in Figure 2, where values from Columns 7 and 9 of Table 1 are plotted as abscissas and ordinates, respectively. If exact agreement existed between visual estimates and the results of photogrammetric analysis, then all points would lie on a straight line with a 45° slope. The points plotted in Figure 2 scatter fairly well about a straight line which has a slope somewhat greater than 45°. The average deviation of the points from the line is expected to decrease as the number of points is increased. It should be noted that each stereophotograph covers a limited field of view compared with the field of view of the shipboard observer (Fig. 3).

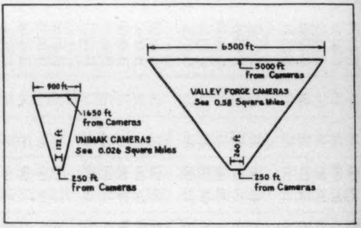

FIG. 3 – Ocean perspectives seen by stereocameras on *Unimak* and *Valley Forge* (areas indicated are fixed by properties of cameras, film, stereoplanigraphs, and camera separation).

It is considered that Figure 2 shows good correlation between the visual estimates and quantitative height determinations made from the stereophotographs. Individual estimates may not be accurate, but when the number of estimates is large the correlation is good.

The *Unimak* data and the *Valley Forge* data do not indicate divergent trends, that is, although the observers on the *Unimak* and the *Valley Forge* used slightly different criteria for observing waves, their results are substantially identical.

The visual observations on which the long-term distributions given later in this report are based, comprise between 11,000 and 18,000 separate observations for each ocean station. It is concluded

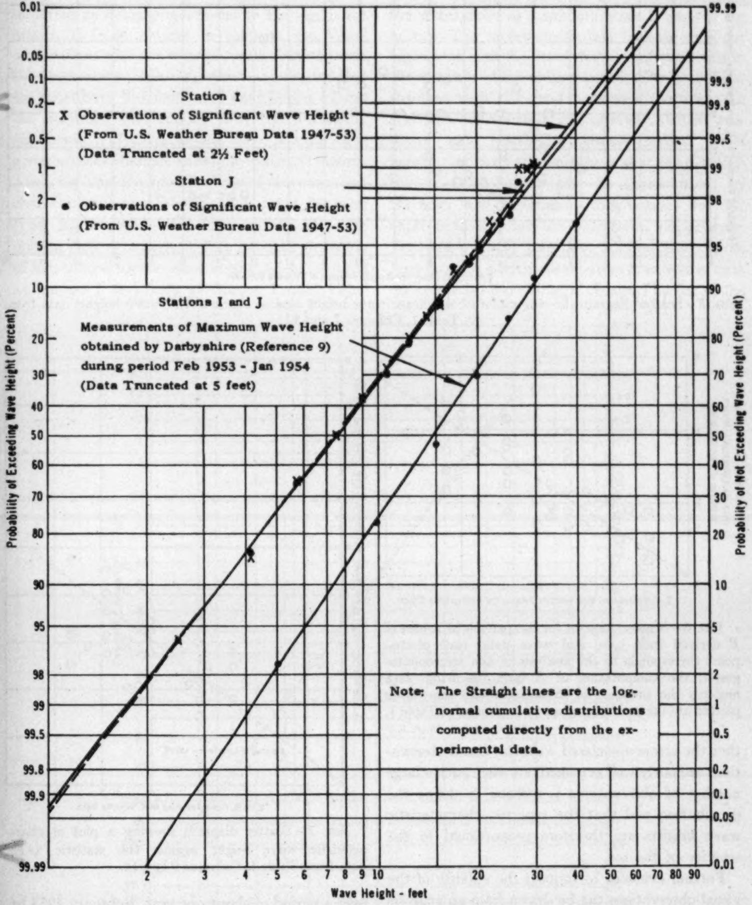

FIG. 4 – Comparison of wave-height distributions derived from visual observations and from measurements of wave heights at Atlantic Ocean Stations I and J; the distribution fitted to the Darbyshire data corresponds to a standard deviation of 0.57 for log$_e$ (maximum wave height) and a median value of the maximum wave height equal to 15 ft.

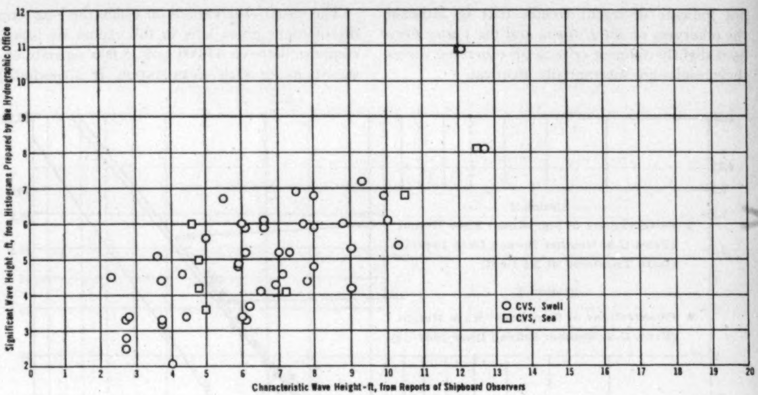

FIG. 5 - Scatter diagram showing a plot of significant wave height against characteristic wave height; data from Table 1, Columns 7 and 12

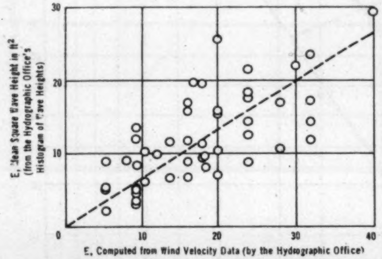

FIG. 6 - Scatter diagram for comparison of values of *E* derived from wind and wave data; each plotted point corresponds to the analysis of one stereophotograph; the computation of *E* from the wind data neglects the presence of decaying swell; the values plotted are taken from the last two columns of Table 1.

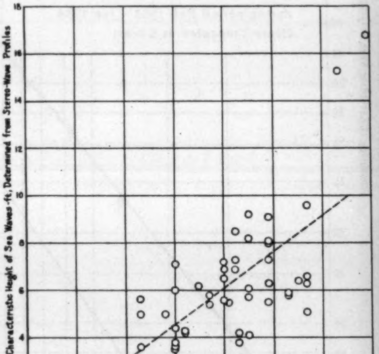

FIG. 7 - Scatter diagram showing a plot of characteristic wave height against the statistic $\sqrt{E}$; data from Table 1, Columns 9 and 14.

that the errors associated with the visual observations are fairly well averaged out when such a large number of observations is utilized to define the distribution and that the reported characteristic wave heights are therefore proportional to the severity of the sea.

Further evidence to support the validity of the visual observations can be drawn from an analysis of measurements of wave height made by *Darbyshire* [1955] by means of a wave meter installed on a weather ship. These measurements were made over a period of about one year, February 1953 to January 1954, at North Atlantic Weather Stations I and J (Fig. 4). Darbyshire reported the maximum wave height for each three-hour period for which visual wave observations were made while the ship was at sea. The visual observations made by weather observers are reported as the 'characteristic' wave height. In the discussion of Figure 5 in the following section, the characteristic height is indicated as being proportional to the significant height. It is of interest to compare the visual observations with the measurements obtained with the wave meter. If the hypothesis is accepted that the short-term distribution of wave height follows the Rayleigh distribution, then the maximum, significant, and characteristic wave heights for a given sea condition are related by constant factors. Thus, the long-term distributions of maximum and characteristic wave heights should be of the same type, log-normal in this case, and should differ only in their mean values. The standard deviation of $\log_e$ (characteristic wave height in feet) is 0.622 at Station J and 0.612 at Station I from visual observations, as compared with a value of 0.57 for $\log_e$ (maximum wave height) for the measurements at Station I and J reported by Darbyshire (Fig. 4). A log-normal distribution has been fitted to the wave-meter data on the assumption that the distribution of maximum wave heights is log normal. The experimental data indicate excellent agreement with the fitted distribution, well within the accuracy of the measurements. The latter fact, together with the good agreement between the standard deviations of characteristic (visual estimates) and maximum (measurements) wave heights, supports the hypothesis that the distribution of wave heights may be approximated by Rayleigh and log-normal distributions for the short term and for the long term, respectively. *Darbyshire* [1956] tests the applicability of the long-term log-normal distribution to extensive data on maximum wave heights obtained by use of the

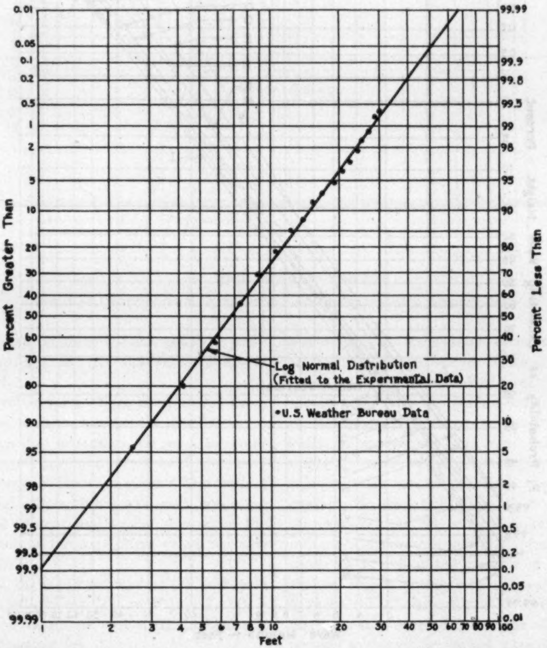

FIG. 8 – Distribution of characteristic wave heights at Station C

British wave meter. He concludes that the logarithmic law appears to be a useful guide to determine the incidence of a particular wave state at a given location.

It is concluded on the basis of the foregoing discussion that the visual estimates by weather observers of sea state, reported as a 'characteristic' wave height, may be used with confidence in establishing distribution patterns such as are given in a following section.

Comparison of wave statistics—It is of interest to utilize the wave data obtained during the sea tests of the *Valley Forge* and the *Unimak* to gain some insight into the validity of a few of the assumptions often made in the forecasting and analysis of ocean waves. For this purpose, the following items were computed:

(a) The characteristic wave height was determined from the wave profiles.

(b) The wave profiles were analyzed statistically to obtain the frequency distribution of individual wave heights and of the corresponding wave lengths above a certain cutoff length, which is that wave length below which lies three per cent of the area under the power spectrum.

(c) The mean value of the squares of all individual wave heights corresponding to waves longer than the cutoff length was determined from the data obtained under (b). These values are denoted by the symbol E, and are listed in Table 1.

(d) The average value of the upper third of the waves having the largest magnitudes (significant wave height) was determined from the data obtained under (b).

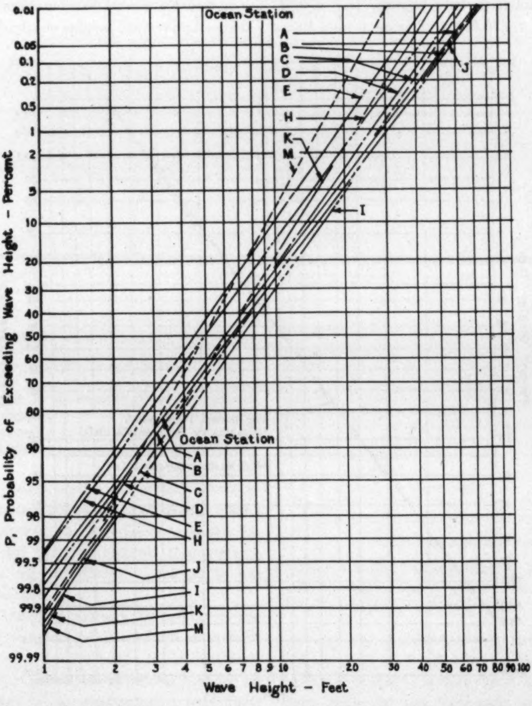

FIG. 9 – Distribution of characteristic wave heights for ten ocean stations

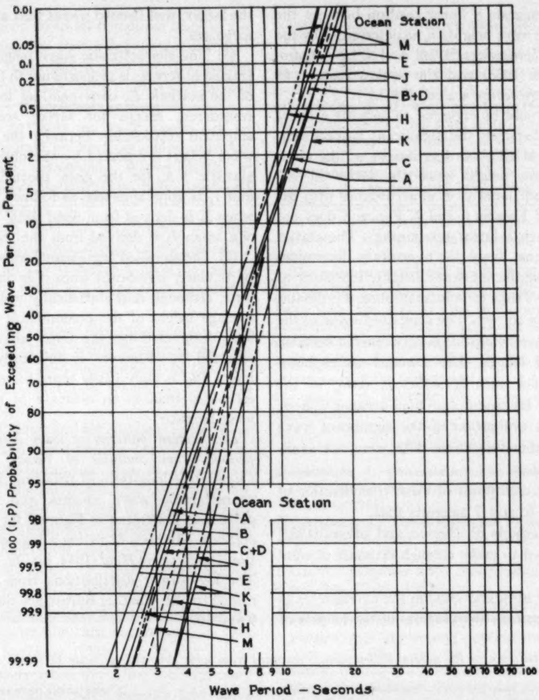

FIG. 10 – Distribution of characteristic wave periods for ten ocean stations

(e) The average value of the characteristic wave heights determined by the shipboard observers was tabulated.

(f) The Hydrographic Office computed a theoretical value of *E* on the basis of the distribution of wind velocities that generated the sea. This computation does not take account of swell that may have been present in the wave system. The method of *Pierson* and others [1955] was used, according to which *E* is proportional to the area under the power spectrum of the sea. These values are also given in Table 1.

In Figure 2, (a) is plotted against (e). In Figure 6, (c) is plotted against (f). In Figure 7, (a) is plotted against the square root of (f). In Figure 5, (d) is plotted against (e).

Figure 2 indicates that trained shipboard observers can, on the average, estimate the heights of the predominant waves reasonably well.

The value of *E* determined from the wind data should agree with the *E* obtained from the wave profiles provided the power-spectrum theory is valid, a narrow sea spectrum exists, swell is negligible, and the stereophotograph covered a representative area of the ocean. One may expect considerable deviations from these assumptions; for example, the sea surface profiles sometimes indicate considerable deviation from a narrow spectrum as well as the presence of swell. Nevertheless, Figure 6 suggests a linear relationship between the *E*'s determined by two independent methods. It is concluded that the wind data may be used to determine the sea state, at least qualitatively.

Figure 7 suggests a linear relation between the characteristic wave heights *h*, as determined by the methods of *Darbyshire* [1956] and *U. S. Hydrographic Office* [1955] and the square root of *E*, except for very severe sea conditions.

Figure 5 would be expected to indicate a linear relationship between the significant wave height and the visual shipboard estimates of the characteristic wave height since the latter is presumably proportional to *E* in accordance with the indications of Figures 6 and 7. Figure 5 does not contradict such a linear relationship. The scatter of values is most likely due to errors in determination of the significant wave height, inasmuch as Figure 2 shows that the visual shipboard estimates are reasonably correct. The computed value of the significant wave height (*d*) is very much a function of the cutoff length. The *Unimak* stereophotographs did not furnish sufficient data, in the opinion of the Hydrographic Office oceanographers, to permit an evaluation of the significant wave height; and therefore these data were not available for the plots.

From an overall point of view, consideration of Figures 2, 5, 6, and 7 suggests that

(1) The methods of *Pierson* and others [1955] may be applied to make a rough estimate of wind waves.

(2) Trained observers can, on the average, make reasonably accurate observations of the heights of the larger, well-formed waves that are present in a given sea.

(3) The characteristic wave height reported by trained observers is proportional to the square root of the statistic *E*, corresponding to the sea state considered, except for severe sea states. The empirical relationship between the characteristic wave height *h* reported by the observers and the statistic $\sqrt{E}$, for the data plotted in Figures 6 and 7, is approximately as follows $h = 1.53\sqrt{E}$ when *E* is derived from wind data, and $h = 1.88\sqrt{E}$ when *E* is derived from the wave data.

(4) The so-called 'significant' wave height is not particularly significant since it is difficult to compute, although it is statistically well defined. The average height of the predominant wave heights, here designated by the term 'characteristic,' as reported by observers, is physically more meaningful and is more easily reproduced on repetitive estimates than is an estimate of the significant wave height.

Distribution patterns of wave heights and wave periods from analysis of visual observations—Cumulative long-term distribution patterns of the characteristic wave heights and periods were plotted as illustrated in Figure 8 for the ten ocean stations. Methods of fitting a log-normal distribution are given by *Hald* [1952, pp. 29, 34–35, 62–63]. The log-normal distributions from the data furnished by the Weather Bureau are shown in Figures 9 and 10.

M	66 00	02 00	Jan. 49	Dec. 53	14,324	4.99	1.608	0.2344	Jan. 49	Dec. 53	14,188	6.99	1.946	0.0676

Note: The statistical computations are based on truncated data. The truncation point is 2.5 ft for wave heights and 5 sec for wave periods.

[a] Logarithms are to the base *e*.

The rather good fit of all computed lines to the plotted data suggests that a log-normal distribution is a good approximation to the distribution pattern of characteristic wave heights and periods for values above the truncation point.

Distribution patterns for wave length can be derived from the data for wave periods by applying an approximate conversion: Wave length = constant × (wave period)^2. For fully developed waves the constant is 3.4.

It is apparent that the distribution of wave lengths will be log-normal if that for the periods is log-normal, since the conversion involves only a change in mean value and slope from the distribution of the periods.

In Table 2 mean values and variances are given for the wave height and period data reported from each ocean station. Also the latitudes, longtitudes, and observation periods over which the data were collected are shown.

Summary—Frequency distribution patterns of wave heights and wave periods may be approximated by a one-parameter type of distribution function when the environmental conditions are steady, whereas they will tend to follow the two-parameter logarithmically normal distribution when the environmental conditions are allowed to vary over a wide range. It should be emphasized that the log-normal distribution illustrated in Figure 8 is influenced much more by the usual sea conditions than by the rare occurrences of very high or very low seas. Thus one should expect greater deviations from the fitted line for very small and very large wave heights and wave periods than for those heights and periods which occur more frequently. It is concluded that the long-term distributions of wave height and wave period may be approximated by the log-normal distribution.

Reasonably accurate visual estimates of wave height can be obtained from trained observers, provided a number of independent estimates are averaged. A single estimate may be considerably in error.

Acknowledgments—The research given in this paper was carried out by the David Taylor Model Basin. It would not have been possible without the cooperation of many persons on board the *Valley Forge* and *Unimak*, on the Coast Guard and Navy staffs, in the Weather Bureau, at the Hydrographic Office, at the Naval Photographic Interpretation Center, and at the Taylor Model Basin.

Wilbur Marks of the TMB staff assisted in the oceanographic planning and analysis. The camera installations were made by C. E. Lemich of the Taylor Model Basin. B. M. Wigle and R. J. Dominic, also of the Taylor Model Basin staff, sorted and matched the many photographs and assisted in analyzing the stereograms and in developing the plotted figures. The stereograms were developed by John Davis and John Boyle of the Hydrographic Office and Photographic Interpretation Center, respectively. Much encouragement has been given to the overall program, of which this study is a part, by John Vasta of the Bureau of Ships.

The paper was reviewed by E. H. Kennard, R. T. McGoldrick, and Mary C. Crook of the Taylor Model Basin staff. The authors wish to express their sincere appreciation to the persons mentioned here and to the many others whose assistance made this work possible.

The opinions or assertions in this paper are the private ones of the authors and are not to be construed as official or reflecting the views of the Navy Department.

Yield of Sediment in Relation to Mean Annual Precipitation

W. B. LANGBEIN AND S. A. SCHUMM

Abstract—Effective mean annual precipitation is related to sediment yield from drainage basins throughout the climatic regions of the United States. Sediment yield is a maximum at about 10 to 14 inches of precipitation, decreasing sharply on both sides of this maximum, in one case owing to a deficiency of runoff and in the other to increased density of vegetation. Data are presented illustrating the increase in bulk density of vegetation with increased annual precipitation and the relation of relative erosion to vegetative density.

It is suggested that the effect of a climatic change on sediment yield depends not only upon direction of climate change, but also on the climate before the change. Sediment concentration in runoff is shown to increase with decreased annual precipitation, suggesting further that a decrease in precipitation will cause stream channel aggradation.

Introduction—The yield of sediment from a drainage basin is a complex process responding to all the variations that exist in precipitation, soils, vegetation, runoff, and land use. This study is aimed only toward a discernment of the gross variations in sediment yield that are associated with climate as defined by the annual precipitation. Such a study may contribute to an understanding of the effects of climatic change on erosion and of the regional variations in sediment yield. Data on sediment yields are now available in sufficient number for this kind of study, although still quite deficient in geographic coverage. Two major sources of sediment data exist. Records collected at about 170 gaging stations of the U. S. Geological Survey, where sediment transported by streams is measured, is one source of data; whereas, the other source of data is provided by the surveys of sediment trapped by reservoirs. Both kinds of data are used in this study.

Precipitation data—Precipitation is used as the dominant climatic factor in the study of sediment yield, because it affects vegetation and runoff. However, the effectiveness of a given amount of annual precipitation is not everywhere the same. Variations in temperature, rainfall intensity, number of storms, and seasonal and areal distribution of precipitation can also affect the yield of sediment. For example, *Leopold* [1951] in an analysis of rainfall variation in New Mexico, found that despite the absence of any trend in annual rainfall, changes in the number of storms produced a significant influence upon erosion. Although analyses of these effects are beyond the scope of this study, the effect of temperature, which controls the loss of water by evapotranspiration, can be readily taken into account. As is well known, the greater the temperature, the greater are the evapotranspiration demands upon soil moisture; hence, less moisture remains for runoff. More precipitation is required for a given amount of runoff in a warm climate than in a cool climate. Therefore, instead of using actual figures of annual precipitation, it is preferable to use figures of precipitation adjusted for the effect of annual temperature. However, in lieu of carrying out these extended computations, it appears possible to use the data on annual runoff which already reflect the influence of temperature. Annual runoff data are available for all the gaging station records and for most of the reservoir records. Because of the well-established relationships between annual precipitation and runoff, it is readily possible to estimate precipitation from the runoff figures.

We shall define effective precipitation as the amount of precipitation required to produce the known amount of runoff. Figure 1 shows a relationship between precipitation and runoff based on data given in Geological Survey Circular 52 [*Langbein*, 1949]. This graph has been used to convert known values of annual runoff to effective precipitation, based on a reference temperature of 50°F. In a warm climate, with temperature greater than 50°, the precipitation so estimated would be less than the actual amount of precipitation; in a cool climate, the effective precipitation so estimated would be more than the actual amount. This is the desired relationship.

Sediment-station data—In recent years a number of records of sediment yield, as measured at sediment-gaging stations, have become available. Annual loads were computed for about 100 stations giving preference to the smaller drainage areas in any region. All parts of the country,

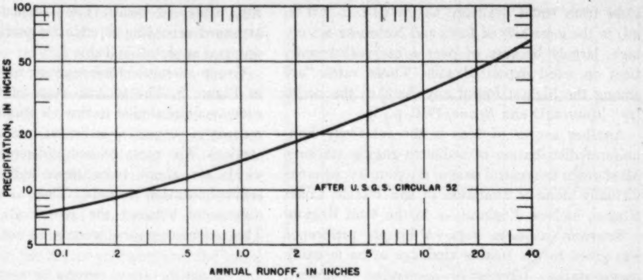

FIG. 1 – Relation between annual precipitation and runoff for a mean temperature of 50° F

where sediment records are collected, are represented.

The annual sediment loads were first arranged according to effective precipitation. They were next assembled into the class groups shown in Table 1, and the arithmetic averages were then computed for each group. Within any group the loads may vary tenfold, reflecting geologic and topographic factors not considered in this study. Each group mean is subject to a standard deviation of about 30 pct. The group averages are plotted in Figure 2. The curve shown was fitted to the data, subject to the condition (1) that it did not depart more than one standard deviation (30 pct) from any of the plotted group means, and (2) that it show zero yield for zero precipitation.

There is considerable opportunity for bias in the figures for load, because the relatively few records prohibit any high degree of selectivity. Few of the rivers drain areas in their primeval environment and moreover, land use can greatly affect the sediment yield. Farming, grazing, road construction, and channelization tend to increase sediment yield; reservoirs impound and, therefore, delay the movement of sediment. If these effects are uniform countrywide, then the overall results might be free of bias in the statistical sense, even though the absolute magnitudes may not be representative of primeval conditions. However, there is considerable variation, particularly with respect to intensity of agricultural operations, which perhaps are most intensive in the midcontinent region. The effects of various kinds of land use upon erosion vary with climate, physiography, soil type, and original vegetation. One surmises that the effect of cultivation is greater in the humid region, where effective precipitation is more than about 30 inches, because of the great contrast between original forest cover and tillage. The erosive reaction of some soil types to cultivation is evident for some small drainage basins in the humid region, which have sediment yields that approach or exceed those usual even in the arid country and are far above those to be expected within their particular range of annual precipitation. For example, sediment

15 to 20	18	17.5	550
20 to 30	20	24	550
30 to 40	15	35	400
40 to 60	15	50	220

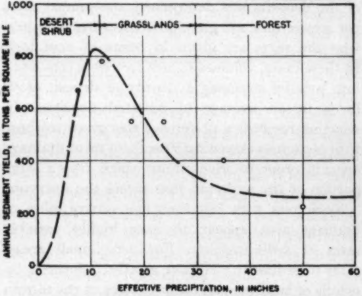

FIG. 2 – Climatic variation of yield of sediment as determined from records at sediment stations

yield from small drainage basins (0.1 to 1.0 sq mi) in the loess hills of Iowa and Nebraska is very high, largely because of poor conservation practices on wind deposited soils. These rates "are among the highest found anywhere in the country" [*Gottschalk* and *Brune*, 1950, p. 5].

Another source of bias is the relatively nonuniform distribution of sediment-gaging stations. Most are in the central part of the country, whereas virtually none is available in the Pacific Coast Region, in New England, or in the Gulf Region.

Reservoir sediment data—Although preference was given to the smaller drainage areas in using gaging-station records of suspended sediment, opportunities for choice in this regard were severely limited. Fortunately, surveys of sedimentation in reservoirs are more numerous, so that there was opportunity to be more selective in choosing reservoirs below small drainage areas, which on that account were presumed to be more indicative of sediment yield nearer the source. Data on reservoir sedimentation were compiled by the *Federal Inter-Agency River Basin Committee* [1953]. Rates of sedimentation were obtained from surveys of sediment accumulation, expressed as an annual rate in acre feet or tons per square mile of drainage area. For those reservoirs where the bulk density of the deposits was determined, the annual rates per square mile are given in terms of tons, otherwise the rates are given in terms of acre feet. In these cases, volumes in acre feet were converted into tons by assuming a density of deposit of 60 lb/cu ft, an average of reported densities. In selecting reservoirs, preference was given to those with capacities exceeding 50 ac ft/sq mi of drainage area, in order to select those which trap a large portion of the sediment that enters the reservoir.

Reservoirs with less than five square miles of drainage area appear to have highly variable rates of sedimentation. For very small areas, rates of sediment yield are greatly influenced by details of land use and local features of the terrain [*Brown*, 1950]. For this reason, reservoirs having drainage areas between 10 and 50 sq mi were used. Because no reservoirs in desert areas were listed in the Inter-Agency compilation, data for desert reservoirs were obtained from unpublished records collected by the U. S. Geological Survey. However, because these reservoirs were on drainage areas of ten square miles or less, rates of sediment yield for these desert reservoirs were adjusted downward to obtain equivalent rates from drainage areas of 30 sq mi, according to the 0.15 power rule explained below. The sediment data were arranged according to effective precipitation and grouped as shown in Table 2.

Group averages of the reservoir data are plotted in Figure 3. The general shape of the resulting curve is quite similar to the one obtained from the records of suspended sediment measured at river stations. The most evident difference is that the yields are about twice those indicated by the sediment-station records. There are significant differences between the two kinds of records. The sediment-station records do not include bed

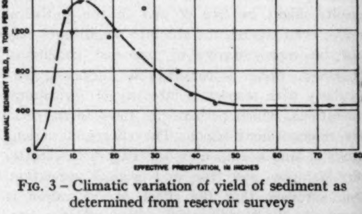

FIG. 3 – Climatic variation of yield of sediment as determined from reservoir surveys

load, which, being the coarser fraction of the load, is trapped by a reservoir. The effects are variable depending on relative amounts of bed and suspended loads at gaging stations and on the trap efficiency of the reservoirs. Moreover, reservoirs are generally built in terrain that offers favorable sites, which means drainage basins with steep slopes and hence higher rates of net erosion. However, in the comparison made here most of the difference is probably due to the effect of size of drainage area. Several studies have shown that sediment yields decrease with increased drainage area, reflecting the flatter gradients and the lesser probability that an intense storm will cover the entire drainage basin. Assuming that the graphs shown by *Brune* [1948] are correct for this effect, rates of sediment yield are inversely proportional to the 0.15 power of the drainage area. Noting that the drainage areas used for Figure 2 average about 1500 sq mi and those for Figure 3 about 30 sq mi, the sediment yields for reservoir data should average about $(1500/30)^{0.15}$, or 1.8 times that for the sediment-station data. This correction applied to the reservoir data would very nearly account for most of the difference between the curves of Figures 2 and 3.

Figures 2 and 3 appear to show a maximum sediment yield at about 12 inches annual effective precipitation, receding to a uniform yield from areas with more than 40 inches effective precipitation. The lack of data for climates with less than 5 inches of annual precipitation makes it difficult to determine the point of maximum yield with accuracy. Available data indicate, however, that it is at about 12 inches or less.

In a similar study of erosion rates and annual precipitation for large rivers of the world (Fig. 4), *Fournier* [1949] notes that the drainage basins are located on a parabolic curve in relation to their climatic character. For example, the upper limb of the parabola (greater than 43 inches) is formed by rivers typical of a monsoon climate: Ganges, Fleuve Rouge (Hung Ho), Yangtze, and some basins of southeastern United States; the middle segment of the curve between 24 and 43 inches of rainfall is formed by drainage systems located in regions with essentially equally distributed annual rainfall, as the Atlantic coastal rivers of the northeastern United States; the lower limb of the curve below 24 inches is formed by rivers draining regions of the more continental steppe or semiarid climates: Vaal, Indus, Rio Grande, Hwang-Ho, Tigris, and Colorado. Fournier concluded that the regions of maximum erosion are those in which monthly rainfall varies greatly, the monsoon and steppe climates.

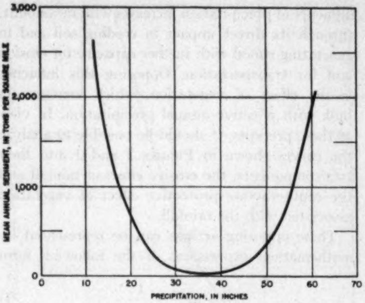

FIG. 4 – Relation of sediment yield to precipitation [after *Fournier*, 1949]

The midpart of his curve shows an annual yield of only five to seven tons per square mile which Fournier attributes to basins in which rainfall is uniform throughout the year such as those in the northeastern United States. These figures are much below that indicated by the few available records in that region which range from a minimum of about 40 tons/sq mi for Scantic River in Connecticut to 370 tons/sq mi for Lehigh River in Pennsylvania.

The lower limb of Fournier's curve terminates at a precipitation of about 12 inches, reaching an annual yield of about 2500 tons/sq mi. Although rates as high and even higher occur in many areas in the arid country, the figure of 2500 tons/year seems somewhat high as an average. The upward trend cannot continue if there is zero sediment yield (in rivers) for zero precipitation; the curve seemingly must reverse its upward trend and swing downward towards the origin.

The upper limb of Fournier's curve (above 43 inches precipitation) shows sharply increasing sediment yield with increasing precipitation, a trend that is not evident in Figures 2 and 3. However, it is possible that additional information in such areas of great rainfall as northern California and the Pacific Northwest may introduce an increasing trend in this part of those graphs.

Analysis of the climatic variation in sediment yield—The variation in sediment yield with climate can be explained by the operation of two factors each related to precipitation. The erosive influence of precipitation increases with its amount, through its direct impact in eroding soil and in generating runoff with further capacity for erosion and for transportation. Opposing this influence is the effect of vegetation, which increases in bulk with effective annual precipitation. In view of these precepts, it should be possible to analyze the curves shown in Figures 2 and 3 into their two components, the erosive effect of rainfall and the counteracting protective effect of vegetation associated with the rainfall.

These opposing actions can be represented by mathematical expressions of the following form

$$S = aP^{m} \frac{1}{1 + bP^{n}} \tag{1}$$

in which S is annual load in tons per square mile, P is effective annual precipitation, m and n are exponents, and a and b are coefficients. The factor aP^{m} in the above equation describes the erosive action of rainfall in the absence of vegetation. The die-away factor $1/(1 + bP^{n})$ represents the protective action of vegetation. The factor aP^{m} increases continuously with increase in precipitation, P, whereas the factor $1/(1 + bP^{n})$ is unity for zero precipitation, and decreases with increases in precipitation.

Eq. (1) can not be evaluated by the usual least-squares method. Hence it was evaluated by trial and error, graphical methods yielding the following approximate results.

$$S = \frac{10P^{2.3}}{1 + 0.0007P^{3.33}}$$

for sediment station data and

$$S = \frac{20P^{2.3}}{1 + 0.0007P^{3.33}}$$

for reservoir sediment data.

The factor $P^{2.3}$ describes the variation in sediment yield with constant cover. Analyses of measurements of rainfall, runoff, and soil loss made on small experimental plots operated by the Department of Agriculture [*Musgrave*, 1947], indicate that, other factors the same, erosion is proportional to the 1.75 power of the 30-minute rainfall intensity. However, it is rather difficult to draw a connection between the intensity of 30-minute precipitation and annual precipitation. Inspection of *Yarnell's* [1935] charts indicates one relationship exists in the eastern part of the country and another in the western areas. However, in both areas 30-minute intensities vary with annual rainfall to some power greater than unity. Hence, one can conclude that erosion will vary regionally to some power of the annual precipitation greater than 1.75.

The second factor, $1/(1 + 0.0007\ P^{3.33})$, equals $S/aP^{2.3}$. This function, as graphed in Figure 5, purports to isolate the variation in sediment yield caused by differing degrees of vegetative cover. This function varies as shown in Table 3.

There is a good deal of information on the relation between different vegetal covers and rates of erosion in a given climate. However, most of this information deals with cultivated lands and

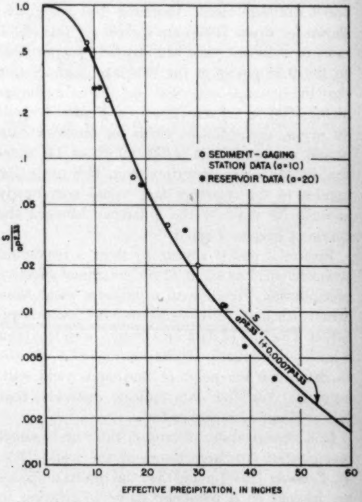

FIG. 5 – Decrease in relative sediment yield with increasing precipitation

50	Forest	0.003

[a] Associated with effective precipitation.

few of the vegetal data are in quantitative terms. *Musgrave* [1947] attempted a quantitative evaluation of relative erosion based on data collected at experimental watersheds in the Pacific Northwest. The results agree quite well with the results given in Table 3.

Cover	Relative erosion
Row crops or fallow	1.0 to 0.60
Small grains, grass hayland, crested wheat grass	0.05
Pasture, excellent condition, and forests	0.01 to 0.001

Formula (1) may be generalized as

$$S \propto R/V \qquad (2)$$

where R is annual runoff, and V is mass density of vegetation. In any given region the two factors operate separately; thus, sediment loads may vary with runoff depending on land use and vegetal conditions. For example, *Brune* [1948] shows that, for a given land condition in the Midwest, sediment yield increases with runoff, and that, for a given runoff, sediment yield varies enormously with percent of tilled land. The present study, however, treats of the broad climatic variation in which both runoff and vegetation are each uniquely related to effective precipitation.

With increasing precipitation, sediment yield varies as shown on Figures 2 and 3, but runoff increases as shown on Figure 1. The ratio between sediment yield and runoff is a measure of the concentration. This quantity is generally reported in parts per million (ppm) by weight and may be computed by dividing sediment yield in tons per square mile by runoff computed in tons per square mile. Figure 6 shows results of this computation for the data in Table 2. The concentration decreases sharply with increasing precipitation.

Annual precipitation, as indicated by the annual runoff, is used as the sole climatic measure. We have considered differences in precipitation intensity and its seasonal distribution only so far as these influences are reflected in the amount of annual runoff. For example, low precipitation regimes are characteristically more variable than those of humid regions [*Conrad*, 1946], and, indeed, the short-period excesses in intensity show up in the runoff. However, we repeat, as we wrote in our introduction, that although climatic influences on sediment are more complex, a good deal can be learned from consideration of the annual precipitation.

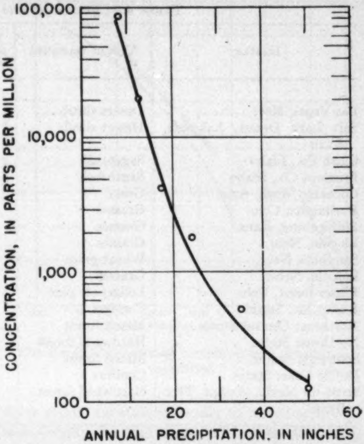

FIG. 6 – Variation of concentration with annual precipitation

Precipitation and vegetation—There can be no question of the highly significant effect of vegetation on erosion. For this reason, we have assembled information on climatic variation and vegetal bulk. The information on vegetal bulk contained in Table 4 was obtained mainly from published sources, ranging in reliability from carefully weighed quadrats to forest statistics and two estimates based on examination of photographs (for references, see Table 4). However, considering the more than 1000-fold variation in vegetal weight, as between desert shrubs to forests, great precision does not seem to be needed for the rough kind of study that seems possible at this time. Some of the data on vegetal weights were given directly in pounds per acre or equivalent. The forest data were obtained by dividing the reported cubic-foot volumes of saw-timber and pole-timber trees, given in millions of cubic feet for each state, by the respective forest area in acres. Unit weights of 45 lb/cu ft were used for hardwoods, 35 for soft woods, and 40 for mixed forests.

Table 4 also includes data on mean annual precipitation and temperature applicable to each case. The climatologic data were not usually given in the references cited and were obtained from U.S. Weather Bureau reports.

Figure 7 shows a plot of precipitation against

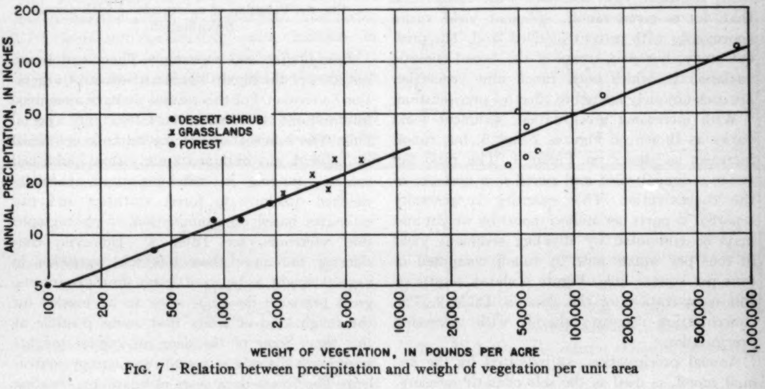

FIG. 7 – Relation between precipitation and weight of vegetation per unit area

vegetation weight. For the data available, the correlation seems quite high with a decided break between forest and nonforest types. The graph indicates that for equivalent rainfall, forests have about five times as much weight as grasses. With a longer life span, trees should understandably show greater total weight in place, although perhaps the annual growth (= annual decay for equilibrium) would be less than for grasses.

The seeming fact that desert shrubs are on the lower continuation of the line defined by the grasses seems anomalous. In arid and semi-arid regions the increase in vegetal bulk with rainfall rather simply reflects increasing opportunity for a greater number of plants, greater opportunity for each plant to reach maximum development for the species environment, and opportunity for growth of larger species. However, this does not explain the variation of forest bulk with rainfall greater than needed to satisfy optimum evapotranspiration demands for the climate. Forests are areas of water surplus in the climatic sense, yet vegetal density seems to vary with precipitation and temperature. Among the eastern states, for example, the vegetal bulk per unit area in Maine and North Carolina are about the same. The lesser annual precipitation in Maine appears to be compensated by a lesser temperature; whereas, in North Carolina higher annual precipitation is compensated by a higher temperature. The forested areas of Washington, Oregon, and California have about the same temperature; the forest densities seem to follow precipitation as follows:

State	Precipitation inch	Vegetation lb/ac
Washington	80	177,000
Oregon	60	158,000
California	53	120,000

The variation in unit weight shown in Figure 7 is made up of two components, one due to variation in weight among different communities of the same vegetation type, and that due to variation in weight among different types. The latter is very likely the dominant factor in the relationship on Figure 5. Beyond a certain limiting precipitation, say that for which precipitation is adequate to meet all evapotranspiration requirements, differences in vegetal bulk may reflect not so much growth factors as differences in plant types or associations. The heavy vegetal bulk in the Pacific Northwest, for example, may be the reflection of a difference in plant type rather than a direct effect of precipitation on growth.

We are considering here only gross relations, ignoring rather important variations that might be due to differences in species, topographic setting, or moisture conditions that might favor or discourage growth. For example, there are patches of timber in the valley bottoms, in the Great Plains, with weight densities far exceeding that of the grasslands. The data used to define this relationship are admittedly crude and subject to bias. The forest statistics, for example, generally exclude bark, leaves, flowers, fruit, and most branches. The ratio of these parts to the whole tree decreases with age. The existing data are for stands in various degrees of maturity, and most existing data exclude roots. The ratio of roots to aboveground growth is variable among different kinds of plants and may be a large source of error.

Then again, although one might conceive that the maximum amount of plant material should theoretically be correlative with climate, other factors such as aspect, depth, and nature of soil are of major influence. Ideally, vegetal densities should be studied locally to arrive at a normal density for the regional climate. However, this kind of study would be beyond the scope of this discussion. Only the evident fact that vegetal densities are so variable over the range of climates experienced in this country makes it at all possible to use the existing data.

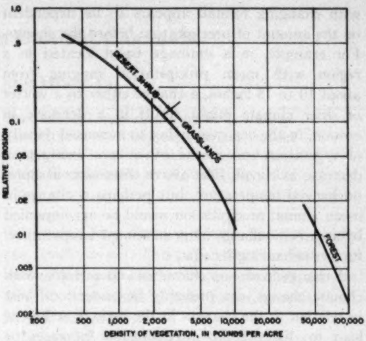

FIG. 8 – Relative erosion compared with density of vegetation

Interpreting the graph in Figure 5 as an indication of relative erosion associated with vegetation, as shown on Figure 7, the relationship shown on Figure 8 can be drawn. According to this graph, a relative change in vegetal density is effective on erosion throughout the climatic range, although the break between trees and grass suggests that per pound, grass is more effective in retarding erosion than trees.

Erosion and climate change—Examination of Figures 2 and 3 may be useful in visualizing not only variations in rates of net erosion between climatic zones in the United States but also the probable change in rates of erosion and stream activity during a climatic change.

Within the 0- to 12-inch precipitation zone an increase in annual rainfall would apparently be followed by an increase in erosion and vice versa; whereas, between about 12 to 45 inches of rainfall, erosion should decrease with increased precipitation. Above 45 inches of precipitation, erosion should remain about constant with increased precipitation, although Fournier's curve (Fig. 4) shows a marked increase in sediment yield above 43 inches of precipitation.

The direction of a change in sediment yield with changing rainfall appears to be dependent on the amount of precipitation before the change. For example, in a drainage basin located in a region with mean precipitation ranging from about 10 to 15 inches, a change either to a wetter or drier climate might result in a decrease in erosion, in the one case owing to increased density of vegetation and in the other case owing to a decrease in runoff. The above discussion assumes unchanged temperature, but perhaps a change in mean annual precipitation would be accompanied by an inverse change in mean annual temperature, further enhancing its effects.

A change in stream character and activity, with climate change, can probably be understood best in relation to the changes in the ratio of sediment load to discharge as precipitation increases or decreases. Referring to Figure 6, it is apparent that as annual precipitation decreases, the concentration of sediment per unit of runoff increases. This suggests quite strongly that, other factors being the same, the increasing sediment loads associated with increasing dryness will cause aggradation, in an amount depending on the magnitude of the climatic change. *Mackin* [1948, pp. 493–495] has summarized changes to be expected in stream activity with changes in load and discharge. In every case, an increase in load or decrease in discharge with constant load results in aggradation and vice versa.

The decrease in annual runoff with decreased precipitation will necessitate an adjustment of stream gradient and shape according to established principles [*Leopold* and *Maddock*, 1953], such that the width and depth of the channel should decrease and gradient increase. These changes are consistent with aggradation. Of course, an increase in precipitation might be expected to result in degradation as sediment concentration decreases. The increased discharge will result in an increase in channel width and depth and a decrease in gradient. Numerous exceptions to the above generalizations can be cited, especially when glaciation, deforestation, cultivation, or a change in base level become important.

Secondary Currents in Straight Channels

H. A. EINSTEIN AND HUON LI

Abstract—The existence of straight uniform flows without secondary current is studied. It is shown that laminar flows of this kind can remain without secondary currents independent of cross section and velocity distribution. For turbulent flows it is shown that secondary flows will develop spontaneously if in any part of the section the expression for $\partial\xi/\partial t$ as given in Eq. (19) is not vanishing.

When the hydraulic engineer speaks of a flow channel he visualizes boundaries confining a flow which is predominantly one-directional. Such flows have been observed to possess a rotation or circulation around an axis parallel to the main flow velocity, transforming it into a helical or multihelical flow. These superimposed rotations are usually called secondary motion. Best known is the occurrence of such secondary currents in bends of pipes and open channels where they are explained by the difference of the centrifugal effects in flow lines of various flow velocities [*Goldstein*, 1938, pp. 84–87].

This explanation does not hold in a straight channel. Since secondary currents have been observed to develop in many straight channels, the authors of this paper felt the necessity of finding a new, and probably basically different explanation of these secondary currents. It is most interesting that such an explanation can be derived directly from the basic flow equations, the Navier-Stokes equations [*Lamb*, 1932, pp. 577–578].

The secondary motion in rivers is important in its effect on bed sediment. It provides for systematic cross motion of the sediment within the channel, concentrating it in some areas in the form of bars and removing it from other areas causing deep scour holes. More apparent to the observer is the concentration of drift wood and drifting ice into individual parts of the river surface. This last effect permits secondary currents to be easily recognized. Less known is the effect of secondary currents on the distribution of the suspended sediment. But even if this effect has not been studied systematically, one must expect its influence to be considerable because of the extremely large size of the effective mixing length.

The basic method of approach—It would be most direct and appropriate to establish the flow equations including secondary currents and to show from these general equations under which conditions such secondary currents have values different from zero. This direct approach has not yielded any results as yet. This paper describes instead an indirect method which tries to establish the conditions under which a flow free of secondary currents is not stable.

In order to eliminate the known effects of various accelerations of the main flow on the secondary currents, the following analysis is restricted to a straight, uniform flow. The generality of the results is not impaired if the x axis is assumed to have the direction of the main flow, while all cross sections are parallel to the yz plane.

The flow equations—Using *Lamb's* [1932, pp. 577–578] nomenclature the Navier-Stokes equations may be written in Cartesian coordinates for an incompressible fluid not affected by outside forces.

$$\frac{Du}{Dt} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \nu\nabla^2 u$$
$$\frac{Dv}{Dt} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \nu\nabla^2 v \tag{1}$$
$$\frac{Dw}{Dt} = -\frac{1}{\rho}\frac{\partial p}{\partial z} + \nu\nabla^2 w$$

Herein u, v, w are the velocity components in the direction of x, y, and z, respectively; p is the pressure, and ν the kinematic viscosity of the fluid. D/Dt is the total derivative moving with the fluid particle and $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$, an operator. The corresponding continuity equation is

$$\partial u/\partial x + \partial v/\partial y + \partial w/\partial z = 0 \tag{2}$$

A more useful form of the equations for the purpose of this paper is obtained if the vorticity is introduced which is defined as a vector with the following three components, which can be expressed more concisely by using indices x, y, z, t to designate partial derivatives

$$\xi = \frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} = w_y - v_z$$

$$\eta = \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} = u_z - w_x \qquad (3)$$

$$\zeta = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} = v_x - u_y$$

Each of these components represents a measure of the instantaneous speed of rotation in the fluid as measured by that of a unit area; ξ for instance, represents the x component of the rotation, as measured by the circulation around a unit square in the yz plane. *Lamb* [1932, pp. 577–578] shows that (1) may be rewritten

$$\frac{D\xi}{Dt} = \xi u_x + \eta u_y + \zeta u_z + \nu\nabla^2\xi$$

$$\frac{D\eta}{Dt} = \xi v_x + \eta v_y + \zeta v_z + \nu\nabla^2\eta \qquad (4)$$

$$\frac{D\zeta}{Dt} = \xi w_x + \eta w_y + \zeta w_z + \nu\nabla^2\zeta$$

with a 'continuity equation' for vorticity applicable in the form

$$\xi_x + \eta_y + \zeta_z = 0 \qquad (5)$$

The correctness of the latter can easily be demonstrated by introducing the definition of the vorticity (3) into (5), and by cancelling identical terms with opposite sign.

The vorticity components as defined by (3) represent the flow circulation around a unit area element at right angles to the particular vorticity component. So is for instance ξ the flow circulation around the unit area in a plane defined by $x =$ const. If ξ is integrated over any arbitrary area of the same x plane, the integral is equal to the flow circulation around the area, or, according to our definition, equal to the secondary current in this area. It is easily visualized from this that the patterns of secondary currents are given in any cross section by continuous areas in which the vorticity ξ has the same sign.

Following the proposed plan, a uniform flow is assumed (characterized by the fact that all partial derivatives of time-average values with respect to x become zero) and for which ξ is equal to zero at a given time. $D\xi/Dt$, or what is equivalent in a uniform flow $\partial\xi/\partial t$ is calculated for this flow. If $D\xi/Dt$ equals zero this flow is stable indicating the possibility of a stable flow free of secondary currents; if it has a finite value this constitutes proof that such a straight uniform flow without secondary currents is impossible.

In order to make the investigation more general a turbulent flow is assumed in which all velocity and vorticity components can be divided into an average value, designated by an overscore, and a deviation from this average, designated by prime, such that, for instance

$$u = \bar{u} + u' \qquad (6)$$

It is clear that the time average of any such deviation becomes equal to zero by definition. The usual assumption is made that not only the time-average of the deviations themselves but also those of the derivatives of the deviations disappear. Now, the first of (4) is transformed in the described way and averaged with respect to time. Note that the first and last term of the right side disappear for $\xi = 0$ because of the previous assumption and $\bar{\xi}' = 0$ as deviation.

$$D\xi/Dt = \bar{\eta}\bar{u}_y + \bar{\zeta}\bar{u}_z + \overline{\xi' u'_x} + \overline{\eta' u'_y} + \overline{\zeta' u'_z} \qquad (7)$$

Using (3), the right side of (7) is rewritten as follows

$$\begin{aligned} D\xi/Dt = {} & \bar{u}_z\,\bar{u}_y - \bar{w}_x\,\bar{u}_y + \bar{v}_x\,\bar{u}_z - \bar{u}_y\,\bar{u}_z + \overline{w'_y u'_x} \\ & - \overline{v'_z u'_x} + \overline{u'_z u'_y} - \overline{w'_x u'_y} + \overline{v'_x u'_z} - \overline{u'_y u'_z} \end{aligned} \qquad (8)$$

In (8) the first term of the right side cancels against the fourth and the seventh against the last. The values w_x and $\bar{v}_x$ are zero according to the assumption of uniform flow leaving only

$$D\xi/Dt = -\overline{w'_x u'_y} + \overline{v'_x u'_z} + \overline{w'_y u'_x} - \overline{v'_z u'_x} \qquad (9)$$

The expression $\overline{(w' u'_y)}_x = 0$ is a derivative with respect to x of an average value. Therefore

$$\overline{w'_x u'_y} = -\overline{w' u'_{xy}} = \overline{w' v'_{yy}} + \overline{w' w'_{yz}} \qquad (10)$$

using the continuity equation (2). Similarly

$$\overline{v'_x u'_z} = \overline{v' w'_{zz}} + \overline{v' v'_{yz}} \qquad (11)$$

Again, using the continuity equation, one can write

$$\begin{aligned} \overline{w'_y u'_x} &= -\overline{w'_y v'_y} - \overline{w'_y w'_z} \\ \overline{v'_z u'_x} &= -\overline{v'_z v'_y} - \overline{v'_z w'_z} \end{aligned} \qquad (12)$$

Introducing (10), (11), and (12) into (9)

$$\begin{aligned} D\xi/Dt = {} & -\overline{w' v'_{yy}} - \overline{w' w'_{yz}} + \overline{v' w'_{zz}} + \overline{v' v'_{yz}} \\ & -\overline{w'_y v'_y} - \overline{w'_y w'_z} + \overline{v'_z v'_y} + \overline{v'_z w'_z} \end{aligned} \qquad (13)$$

The left side of (13) can be rewritten as follows

$$\begin{aligned} D\xi/Dt = {} & \bar{\xi}_t + \overline{\xi'_t} + \overline{u\xi_x} + \overline{u'\xi'_x} + \overline{v\xi_y} \\ & + \overline{v'\xi'_y} + \overline{w\xi_z} + \overline{w'\xi'_z} \end{aligned} \qquad (14)$$

In (14) the second term by definition, and the third, fifth, and seventh disappear, since ξ is assumed to have zero average at the time under consideration. Of the remaining terms, 4, 6, and 8 are expanded using (3).

$$D\xi/Dt = \bar{\xi}_t + \overline{u'w'_{xy}} - \overline{u'v'_{xz}} + \overline{v'w'_{yy}} - \overline{v'v'_{yz}} + \overline{w'w'_{yz}} - \overline{w'v'_{zz}} \quad (15)$$

The first two terms containing u can be transformed again as follows

$$(\overline{u'w'_y})_x = 0 = \overline{u'_xw'_y} + \overline{u'w'_{xy}} = -\overline{v'_yw'_y} - \overline{w'_zw'_y} + \overline{u'w'_{xy}} \quad (16)$$

or

$$\left.\begin{aligned} \overline{u'w'_{xy}} &= \overline{v'_yw'_y} + \overline{w'_zw'_y} \\ \text{and similarly} \qquad & \\ \overline{u'v'_{xz}} &= \overline{w'_zv'_z} + \overline{v'_zv'_y} \end{aligned}\right\} \quad (17)$$

Introducing (17) into (15) and combining it with (13), one obtains

$$\xi_t = -\overline{w'v'_{yy}} - \overline{w'w'_{yz}} + \overline{v'w'_{zz}} + \overline{v'v'_{yz}} - \overline{w'_yv'_y} - \overline{w'_yw'_z} + \overline{v'_zv'_y} + \overline{v'_zw'_z} - \overline{v'_yw'_y} - \overline{w'_zw'_y} + \overline{w'_zv'_z} + \overline{v'_zv'_y} - \overline{v'w'_{yy}} - \overline{w'w'_{yz}} + \overline{v'v'_{yz}} + \overline{w'v'_{zz}} \quad (18)$$

These sixteen terms can be combined as follows

$$\bar{\xi}_t = \frac{\partial^2}{\partial y \partial z}(\overline{v'^2} - \overline{w'^2}) + \frac{\partial^2}{\partial z^2}(\overline{v'w'}) - \frac{\partial^2}{\partial y^2}(\overline{v'w'}) \quad (19)$$

Eq. (19) represents the main result of this study and needs some discussion. The value $\overline{v'^2}$ for instance can be interpreted as pressure fluctuation in the y direction due to turbulence, divided by the constant density of the fluid. Figure 1 shows a pressure diagram on the unit area in the zx plane, $\overline{v'^2}$ is the average pressure, while the marked area gives the deviation from uniform distribution over the area as expressed by the change of $\overline{v'^2}$ in direction z. If the distribution of v'^2 is the same on the left hand and on the right side of the unit square of Figure 1, the unit body is still in equilibrium. If the two distributions are unequal, however, as described by a change of the distribution in direction y, a moment is applied to the body, causing it to change its speed of rotation around the x direction, or in other words, the unit rotation ξ is changed. The same argument applies to the $\overline{w'^2}$ term.

The effect of the two last terms is quite different. The average $\overline{v'w'}$ is well known as a Reynolds stress acting on xy or xz planes in direction y or z, respectively. A first derivative of this stress with respect to z or y, respectively, indicates the change of the shear stress through the unit body of fluid, the resulting force on this body. If a second derivative is found to be in the same direction, the unequal distribution of this force is obtained, which again causes the unit body to change its speed of rotation around the x direction, the rotation ξ.

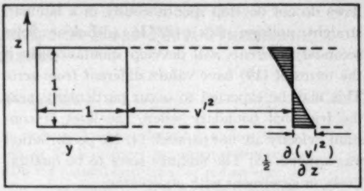

FIG. 1 – Visualization of the term $\frac{\partial(\overline{v'^2})}{\partial z}$

Next the question arises in which flows the various terms of (19) do not vanish. In isotropic turbulence or even near-isotropic turbulence such as near the center of a pipe flow $\overline{v'^2}$ and $\overline{w'^2}$ are equal in magnitude such that the first part does not contribute to the change of ξ. But also the Reynolds stresses are zero in isotropic turbulence and its second derivatives are vanishing everywhere the shear distribution is linear, such as in two dimensional flow or in a circular pipe. It is more difficult to specify where the terms of (19) do not vanish. The difference $(\overline{v'^2} - \overline{w'^2})$ is different from zero mainly near a frictional boundary. The derivative does not disappear in one of the two directions y and z if the flow pattern changes as one follows the boundary in the cross section. This fact can best be characterized by lines of constant velocity in the cross section which are parallel neither to the boundary nor among themselves. The shear terms will contribute to the change of ξ whenever the shear distribution is nonlinear. This again may be expected to occur where the lines of constant velocity are not parallel.

Summary and conclusions—The following conclusions are drawn: (1) The stability of straight uniform flows without secondary currents was studied by determining the change with time of the vorticity in the direction of the main flow. (2) No terms containing average velocity components cause such a change, indicating that secondary flows do not develop spontaneously in a laminar, straight uniform flow. (3) In turbulent flows secondary currents will develop spontaneously if the terms of (19) have values different from zero. This may be expected to occur particularly near the frictional boundary where the lines of constant velocity are not parallel. (4) No perturbation was applied. (5) The findings seem to be qualitatively in agreement with observation.

Conductivity and Length Relationships in Heat-Flow Transducer Performance

DONALD J. PORTMAN

Abstract—In recent years many investigators have used thermoelectric heat-flow transducers to measure heat conduction in natural soil. If the transducer has thermal properties different from those of the soil it will interfere with the natural heat transfer and an error in measurement will occur. An analysis of the error for a transducer placed in an infinite medium in steady-state conditions is made in terms of two non-dimensional parameters: (1) the ratio of transducer conductivity to soil conductivity, and (2) the ratio of transducer thickness to transducer width. An exponential relationship is postulated on the basis of physical considerations and is verified by the results of an electrical analogy experiment for a square transducer having a thickness-width ratio of 0.125 for conductivity ratios from about 0.1 to 2.2. An error of −70 pct was found for a conductivity ratio of 0.1 and an error of +5 pct for a conductivity ratio of 2.2. The results are used to estimate error in measurements made during the Great Plains Turbulence Field Program.

Introduction—A heat-flow transducer, or heat-flow meter, is a device for the direct measurement of heat transfer in one dimension. It usually consists of a thin sheet or plate of insulating material fitted with thermocouple junctions. The latter are arranged so that they form a thermopile having an output proportional to the temperature gradient across the plate. In steady conditions, therefore, the thermopile output is a direct measure of heat conduction through the plate.

In studying evaporation from natural soil, snow, or vegetation-covered surfaces by means of the energy balance a heat-flow transducer may be used to determine heat conduction in the soil. Use of such a device in soil was first reported by *Falkenberg* [1930] who attempted to use a circular Woods metal plate by placing it directly on the soil surface. *Dunkle* [1940] described an improved 'heat meter' made of Bakelite and having about 480 thermocouple junctions placed in a plate one-eighth inch thick and four and one-half inches square. He suggested that it be used in soil as well as in other media to measure heat transfer. *Deacon* [1950] described two transducers for soil heat-transfer measurements. He showed how they could be used by placing them one centimeter or less beneath the soil surface. Since that time transducers of the type described by Dunkle have been used by many investigators. Reference may be made, for example, to *Brooks* and *Kelly* [1951], *Gerhardt* [1957], *Portman* [1957], and *Rhoades* [1957].

Heat-flow transducers have been used for many other purposes, particularly for measuring heat transfer in building walls. They might be used, as well, in dams and other hydrological structures wherever it is desired to measure heat transfer.

Although the use of a transducer is perhaps the simplest and most convenient method of measuring soil heat transfer it is not always without difficulty. An important problem arises from the fact that the transducer acts as a barrier to the movement of soil moisture. Transducers made by Gier and Dunkle for use in soil had a rectangular grid of 25 holes, $\frac{3}{16}$ inches in diameter, equally spaced over the $4\frac{1}{2} \times 4\frac{1}{2}$ inch plate. The holes permitted vertical movement of water and water vapor. It is probable that, for a solid transducer, the barrier effect would decrease as the horizontal dimension of the plate is decreased. Nevertheless, transducers have been found to give relatively accurate information for energy-balance studies in moderately dry soil and for heat transfer at depths where vertical movement of water is negligible.

Another difficulty arises if the thermal properties of the transducer are significantly different from those of the soil. For steady-state conditions, only thermal conductivity and length relationships enter the problem. If the conductivity of the transducer is not equal to that of the soil, the soil heat-flow pattern will be distorted. For a given conductivity inequality the amount of distortion will depend on the width and the thickness of the transducer and the depth of placement in the soil. If there is distortion, the heat flow through the transducer will not equal that in the undisturbed soil for an equal area. It is the purpose of this analysis to determine the effect of conductivity and length relationships in the performance of heat-flow transducers.

Theoretical considerations—The following discussion and conclusions apply to a square transducer in steady-state conditions. It is assumed, moreover, that if the two conductivities are equal, no discontinuity of conductivity exists at the soil-transducer interfaces, and if they are not equal an abrupt discontinuity exists, that is, there is no 'contact resistance.'

With these assumptions it can be physically reasoned that the ratio X of the transducer heat flow q_t to the undisturbed soil heat flow q_s will be determined by the soil conductivity k_s, the transducer conductivity k_t, the transducer width (= length) W, the transducer thickness L, and the depth D of transducer placement. Thus

$$X = q_t/q_s = \phi_1(k_t, k_s, W, L, D) \quad (1)$$

in which ϕ_1 is an unknown function. By inspection it is seen that the five variables can be combined in three non-dimensional ratios for convenience of analysis, and (1) can be written

$$X = \phi_2(k_t/k_s, L/W, D/W) \quad (2)$$

It is apparent that if $k_t < k_s$ then $q_t < q_s$ and if $k_t > k_s$ then $q_t > q_s$. In the former case the transducer offers more resistance to heat flow than does an equal thickness of soil. There will be a tendency, consequently, for heat to flow around the transducer. In the latter case the opposite condition exists so that more heat tends to flow through the transducer than through an equal thickness of soil. Furthermore, an increase in L/W can be thought of as an increase in L holding W constant. Hence, it is obvious that the distortion, as indicated by the deviation of X from unity, will increase with an increase in thickness L. On the other hand, a decrease in L/W can be thought of as a decrease in L holding W constant, and it becomes clear that this would decrease the degree of distortion.

If it is assumed that at the soil surface there exists a uniform heat source or sink, uninfluenced by the nearness of the transducer, it can be reasoned that a decrease in depth will decrease any existing distortion, other factors being constant. A uniform source or sink at the surface implies that the flow lines there are parallel and vertical, that is, perpendicular to the surface. Distortion at the transducer implies that as the transducer is approached from the surface the flow lines tend either to concentrate toward the center of the transducer or to deflect away from it. It can be imagined that as the depth is decreased there can be less deflection, or less concentration, merely because more curvature in flow lines will be required to effect the same distortion. For $k_t < k_s$, as with the case for a wide transducer, resistance for heat to flow through the transducer would be less effective since an increase in curvature means an increase of the path to flow around the transducer. Similar, but converse, reasoning would explain the opposite situation.

The model of a uniform source or sink at the surface seems somewhat unrealistic, however. If a transducer for which $k_t/k_s \neq 1$ were very near the surface, the flow pattern distortion would alter the surface temperature and a uniform source or sink could no longer be assumed to exist. Actually, the energy transfers at the surface could then be expected to be different and the situation would be dependent on external conditions. It is difficult to estimate these effects in rendering the above model invalid.

Because of the last-mentioned difficulty and because a solution of the problem would have application without consideration of the dependency on depth it seems reasonable to consider the case for a transducer placed in an infinite medium for a first analysis. The equation to be solved then is

$$X = \phi_3(k_t/k_s, L/W) \quad (3)$$

Considerable insight on the problem may be gained by establishing the limits of X for various values of k_t/k_s for any L/W. The following inequalities establish the envelope of a family of curves for all values of L/W: For $k_t > k_s$, $q_t > q_s$, and $\Delta T/L < G$, $X > 1$ and $(\Delta T/L)/G < 1$, in which ΔT is the average temperature difference across the transducer and G the vertical temperature gradient in undisturbed soil. Since

$$X = \frac{k_t}{k_s}\frac{\Delta T/L}{G}, \qquad X < \frac{k_t}{k_s}$$

Conversely, for

$$k_t < k_s, \qquad X > k_t/k_s$$

The cross-hatched areas in Figure 1 show the regions in which the curves must lie for all values of L/W. Note that all curves must pass through the points $X = k_t/k_s = 0$ and $X = k_t/k_s = 1$.

The form of a curve within this envelope may be explored with the following reasoning.

From (3) and the defining relationships of q_t

and q_s

$$\frac{\Delta T/L}{G} = \phi_4(k_t/k_s, L/W) \tag{4}$$

and as $k_t \rightarrow 0$

$$\frac{\Delta T/L}{G} = \phi_4(0, L/W)$$

The latter function, $\phi_4(0, L/W)$, must equal or be greater than unity and it must approach unity as L/W approaches infinity. Since in reality L/W ratios for transducers are always smaller than, at most, 0.1, it may be established that $\phi_4(0, 0.1) = A/G > 1$. It follows, then, that

$$X = \frac{k_t \Delta T/L}{k_s G} < \frac{k_t A}{k_s G} \tag{5}$$

in which A has an undetermined value.

Similarly, for k_t approaching infinity

$$X = \phi_5(\infty, L/W) \geqq 1$$

and in this case as $L/W \rightarrow 0$, $X \rightarrow 1$, and as L/W approaches its maximum value 0.1

$$X = \phi_5(\infty, 0.1) = C \tag{6}$$

in which C has an undetermined value.

Hence the areas of Figure 1 are restricted by the above considerations to those indicated in Figure 2. The lines $X = (k_t/k_s)\ (A/G)$ and $X = C$ were arbitrarily placed.

The problem remains of finding the function ϕ_3 in (3) with the conditions that as

$$k_t/k_s \rightarrow 0, \qquad X \rightarrow 0$$

and as

$$k_t/k_s \rightarrow 1, \qquad X \rightarrow 1 \tag{7}$$

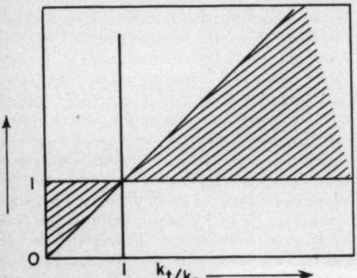

FIG. 1 – Flux ratio limits

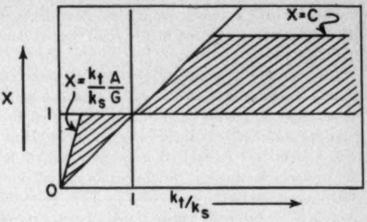

FIG. 2 – Restricted flux ratio limits

The two conditions immediately suggest that ϕ_3 is an exponential function. Hence, taking logarithms, one may write (3) as

$$\ln X = \phi_6(k_t/k_s, L/W) \tag{8}$$

or

$$\ln X = \sum_{n=0}^{\infty} (L/W)^n \psi_n(k_t/k_s)$$

with ψ representing another function. For values of L/W much less than one, powers of L/W may be neglected for a first approximation. Thus

$$\ln X \approx \psi_0(k_t/k_s) + L/W\psi_1(k_t/k_s)$$

but as

$$L/W \rightarrow 0$$

$$X \rightarrow 1$$

$$\ln X \rightarrow 0$$

$$\text{and} \quad \psi_0(k_t/k_s) \rightarrow 0$$

therefore

$$\ln X \approx L/W\psi_1(k_t/k_s) \tag{9}$$

or

$$X \approx e^{L/W\psi_1(k_t/k_s)}$$

From (7) it was found that the function could be expressed as in the following equation

$$X = e^{aL/W(1-k_s/k_t)} \tag{10}$$

in which a is assumed to be a constant greater than zero.

Experimental verification—An electrical analogy experiment was used in an attempt to verify the form of (10) and to evaluate a. The experiment consisted of submerging a model of a heat-flow transducer in a tank of water in which a uniform and steady alternating current potential was maintained. The electrical resistance of the model was varied and, in effect, the current flow through the model was compared to the undisturbed flow in the tank.

This method of verifying (10) was undertaken mainly because the necessary electrical equipment could be readily obtained on loan from the Department of Civil Engineering of Johns Hopkins University. It seemed admirably suited to the problem because of the geometrical and conductivity relationships involved. The analytic approach for the three dimensional case appeared to be particularly cumbersome without an electronic computer since lengthy approximation methods would be required. Furthermore, an analogy method with resistance networks did not seem to offer a very direct approach.

The experimental technique and the electrical system employed have been described by *Li* and others [1954] who used the same equipment to solve a water-flow problem. The physical system consisted of three components: (1) an alternating current source of about 800 c/s, (2) a combined potentiometer and Wheatstone bridge arrangement with earphones and probe, and (3) the electrolytic tank, its electrodes and the model.

Alternating current is required for an experiment of this type to avoid deposition of the electrolyte at the electrodes. An audio frequency is employed so that the experimenter can use earphones instead of a galvanometer, enabling him to locate equipotential lines in the electrical field by merely listening for a minimum tone. The potentiometer circuit was used in this case to measure the average potential difference between the two sides of the transducer model and to determine the potential drop over an equal interval in an undisturbed portion of the tank. The Wheatstone bridge served to evaluate the total resistance of the model and the resistance of the water in the tank.

The potentiometer and bridge were so arranged that a single switch changed the whole system from one for measuring resistance to one for measuring potential, or *vice versa*. The audio frequency source and the earphones and probe were used for both systems. Since the circuit diagrams have been published [*Li* and others, 1954, pp. 807, 808] the electrical system will not be further discussed.

An ordinary rectangular glass aquarium was obtained for the electrolytic tank. It was approximately 25 × 50 cm, and 30 cm deep. The two ends were fitted with flat copper sheets to form electrodes covering each of the inner end surfaces. The tank was filled with tap water which had enough impurities to form an electrolyte of a convenient resistance for the ranges of the bridge and the potentiometer.

Because of symmetry of the flow pattern through and around an imbedded transducer, a model was constructed to represent a quarter section of the transducer. It was attached to the wall of the tank midway between the two electrodes, with its sides parallel to the tank electrodes and its upper edge flush with the water surface. The dimensions of the model were 10 × 10 × 2.5 cm representing, therefore, a transducer with an L/W ratio of 0.125. Essentially, the model was a rectangular container to hold water of different resistivities. It was made of non-conducting materials; the edge material was $\frac{1}{8}$ inch thick and that of the two sides was $\frac{1}{16}$ inch thick. Each side was perforated with 225 holes in a rectangular grid. A brass machine screw was then turned part way into each hole and the protruding screw ends were sheared off. Consequently electricity could flow perpendicularly but not laterally through the model sides.

The model was filled first with a sample of the tank water and the area around the model was probed to evaluate distortion in the potential field caused by the walls of the model. It was found that the distortion could not be detected with the electrical system employed and it was assumed, consequently, that the effect of the model surfaces could be neglected.

Various concentrations of tap water, distilled water, and salt water were used in the model to obtain the desired conductivity ratios. In each case the potential drop across the sides of the model was determined by measuring the potential at 25 points on each side. Since the equipotential surfaces formed curves at their intersections with the model sides, the average potential of a side could not be determined directly. The potential values were plotted on graph paper, equipotential lines were drawn and the average for the area was graphically determined from the pattern formed.

Resistivities of the tank water and of the various model solutions were determined by placing samples in a non-conducting cylindrical test cell, 10 cm in length and 5 cm in diameter, the ends of which were closed by tightly fitting copper disks which served as electrodes. The resistance R of the cell was measured with the Wheatstone bridge and the resistivity r of each sample determined by

$$r = R(S/l) \quad \text{(ohm cm)} \qquad (11)$$

in which S is the cross sectional area of the cell and l its length.

The ratio of the current flow through the model to the current flow for an equal area in the undisturbed tank water was calculated with the relationship

$$I_m/I_t = (r_t/r_m)(E_m/E_t) \tag{12}$$

in which

I_m = current flow through model

I_t = current flow through an equal area in the tank

r_m = resistivity of model water

r_t = resistivity of tank water

E_m = potential drop across model

E_t = potential drop across distance in tank

Eq. (12) follows from Ohm's law after substitution with the relationship of (11) above. I_m/I_t is the analogue of X in (10) and r_t/r_m the analogue of k_t/k_s.

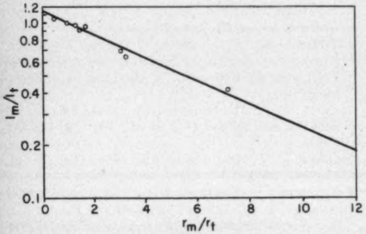

FIG. 3 – Relationship between current flow ratio and resistivity ratio (ordinate on logarithmic scale)

The following data were obtained:

r_t/r_m	I_m/I_t
0.14	0.417
0.30	0.640
0.325	0.689
0.60	0.954
0.67	0.910
0.73	0.970
1.00	1.000
2.23	1.060

Because an exponential relationship was predicted between X and k_s/k_t, their electrical analogues were plotted in semi-logarithmic co-ordinates as shown in Figure 3. It is seen that the experimental points approximate a straight line as expected. The line shown was placed by visual estimation with the requirement that it pass through the point 1.0, 1.0. Its equation is

$$\ln (I_m/I_t) = b(1 - r_m/r_t) \tag{13}$$

in which b is a constant found to be approximately 0.15. Eq. (13), rewritten as an exponential function, becomes

$$I_m/I_t = e^{b(1-r_m/r_t)} \tag{14}$$

which is the analogy of (10). Consequently, $b = a(L/W)$ and substituting $L/W = 0.125$ for the model used in the experiment, $b = 0.15$, and $a = 1.2$. Thus, (10) becomes

$$X = e^{1.2(L/W)(1-k_s/k_t)} \tag{15}$$

Figure 4 shows the curve of (15) for $L/W = 0.125$ and the experimental points obtained. This

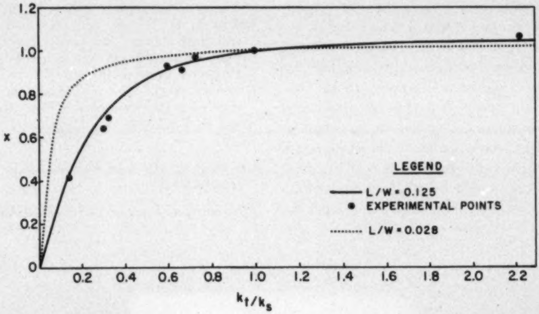

FIG. 4 – Relationship between heat flow ratio and conductivity ratio: $X = e^{a(L/W)[1-(k_s/k_t)]}$

is, of course, merely another representation of the information shown in Figure 3, but it shows also the curve in relationship to the limiting areas discussed earlier.

Application of results—Shown also in Figure 4 is the curve for an L/W ratio 0.028, an appropriate value for a heat-flow transducer used during the Great Plain Turbulence Field Program at O'Neill, Nebraska [*Portman*, 1957]. Since the transducer had steel cover plates approximately $\frac{1}{32}$ inch thick over the $\frac{3}{64}$ inch Bakelite element, the computed curve might not be valid for this case. Steel has a conductivity about 100 times that of the Bakelite, consequently the flow-pattern distortion caused by this transducer would be somewhat different from that of the simple model.

If an overall effective conductivity is used for the transducer, the curve might have meaning. An effective conductivity k_e was computed using the following equation

$$k_e = \frac{L_1 + L_2}{L_1/k_1 + L_2/k_2} \approx 0.0016 \text{ cgs units}$$

in which the subscripts 1 and 2 refer to Bakelite and steel respectively. *Buettner* and others [1957] measured the soil thermal conductivity at the O'Neill test site and have reported that the values at 2.5 cm depth ranged from 0.8×10^{-3} to 1.3×10^{-3} for the observation days for which transducer data are given by *Portman* [1957]. The corresponding k_t/k_e ratios are approximately 2 and 1.2. If the curve is correct for this transducer and if the empirical constant $a = 1.2$ is applicable for an L/W ratio of 0.028, Figure 4 shows that the O'Neill data should have less than +2 per cent error due to flow pattern distortion.

Conclusions—Figure 4 reveals that for conductivity ratios between 0.8 and 2.0 an error of less than five per cent would be involved when a transducer having a thickness-width ratio of 0.125 is used. If the transducer thickness is $\frac{3}{64}$ inch, the standard thickness of a type of transducer commercially available, it could be as small as $\frac{3}{8}$ inch square and have distortion errors no larger than those indicated by the solid line in Figure 4. Such a transducer would be much more satisfactory for use in wet soil than would the larger devices currently being used, because of the moisture barrier problem previously discussed. Several could be used at one depth to obtain more representative measurements and they could, presumably, be connected in series in order to increase the electrical output if necessary.

The analysis shows, further, that if a transducer with an L/W ratio on the order of 0.1 is to be used in soil whose thermal conductivity is likely to change with time it is best to have the transducer conductivity somewhat larger than that of the soil since the error is small and only slowly changing between conductivity ratios of 1 and 2.

Acknowledgments—This contribution is based on a chapter of a dissertation submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy at Johns Hopkins University. The author is indebted to George S. Benton for many suggestions and for helpful criticism in the analysis of the problem.

Interception Losses in Grassy Vegetation

R. H. BURGY AND C. R. POMEROY

Abstract—Studies of the interception process in grassy species are reported for a series of laboratory tests. Procedures, equipment, and techniques were developed to determine the magnitudes of rainfall interception on grasses and to measure the resultant losses. It was found in vigorously growing grass plots that the evaporation of a given amount of intercepted moisture was accompanied by a like reduction in the amount of evapotranspiration from the plants. Total moisture use was approximately the same in plots with wet and dry leaf surfaces. The interception storage component and precipitation passing through the vegetative canopy as combined stemflow, throughfall and drip (STD) were measured to determine the relationships and magnitudes. Storage capacities were observed to agree essentially with those reported by other investigators although some variations can occur with different storm types and intensities. Values of STD were found to be quite significant even at the beginning of small storms.

INTRODUCTION

Savings of water by replacing indigenous brushlands with grass on large acreages in the West are predicated on several basic hydrological relationships. Small watersheds so converted have yielded significant increases in total runoff [*Burgy*, 1958]. This greater water yield may have two explanations: (1) grasses intercept less water than brushy types, and (2) grasses use less water than brush.

Long recognized as important in precipitation disposal is the interception of precipitation by the aerial portion of vegetation, with succeeding disposal into the atmosphere or to the ground. Research in the United States on the interception process in tree-type cover has been considerable, beginning with the classic contributions of *Horton* [1919] and continuing up to the present. Somewhat more limited, yet quite intensive, is work on interception in brush and shrubby vegetation. Still more limited is our knowledge of the interception process in grasses and other low-growing plants.

Precipitation gages of various kinds can be installed in tree types and certain brushy types of vegetation, under the vegetative canopy and adjacent to it, to determine differences in 'ground rainfall.' In low-growing, relatively more dense vegetative types, however, this straightforward method presents obvious mechanical and spatial difficulties.

Clark [1940], in experiments in Nebraska, placed catch pans on the ground beneath grass plants in the field. Low-growing, mat-forming grasses were cut off at the surface and moved to the laboratory, where they were replaced in natural position on screens and then sprinkled. In the field trials, interception was determined by the percentage of rainfall that did not reach the pans. In the laboratory, interception was determined by the portion of water applied that was not recovered beneath the screen. The interception values of Big Bluestem grass varied from 84 pct, with 0.125 inch of rainfall in 30 min, to 47 pct, with 1.0 inch of rainfall in one hour. The low-growing, mat-forming grasses had much lower interception capacities.

In tree or brush types, or in fact any large plant, the flow of water down the stems can be measured by stem collars connected to measuring devices. *Haynes* [1940], working with various crop covers, measured stemflow in that way and also used wax-floored catchment basins to determine stemflow under oats, timothy and blue grass, with erratic results and did not report stemflow.

The inherent difficulty in making measurements for low-growing crops probably accounts for the relative scarcity of information in this field. The obvious need for additional basic data on the interception process in grassland types has led to the present study.

PROCEDURES

It was felt that full evaluation of the interception process in grasses requires a system involving the complete plant-soil-water complex. Equipment and techniques were developed to permit studies of evapotranspirational use by growing plots of grasses subjected to artificial rainfall.

In large tanks of nutrient solution, grasses were planted and grown on test plots constructed of square aluminum frames: a bottom of hardware cloth was attached; excelsior was packed inside the tray and covered with a layer of cheesecloth; and a layer of hardware cloth was attached to the top, forming a sandwich arrangement on which to grow the crop. The individual baskets or plots could be moved to individual weighing pans of nutrient solution resting on scales.

The original weighing mechanism was the scales from a Bendix-Friez weighing-recording rain gage. The pan areas were made ten times as large as the eight-inch rain gage area, expanding the gage scale by ten. But the system did not prove to be accurate enough for the demands of the experiment. Four grocery checkout scales proved more accurate and reliable, although non-recording.

The water-culture technique eliminated the complication of measuring soil-moisture values. The studies were divided into two parts: a series of tests with plots alternately wetted and allowed to dry to determine the total evaporational use (see Section I); and an evaluation of interception storage as distinguished from stemflow, throughfall, and drip (see Section II).

SECTION I

Three different cover types were studied, (1) sunflower plants (used in the initial tests to study methods and techniques), (2) a pure stand of soft chess, and (3) a mixed stand called range mix, consisting of Hardinggrass, alfalfa, narrow leaf trefoil, rose clover, crimson clover, subclover, soft chess, orchard grass, smilo, and tall fescue.

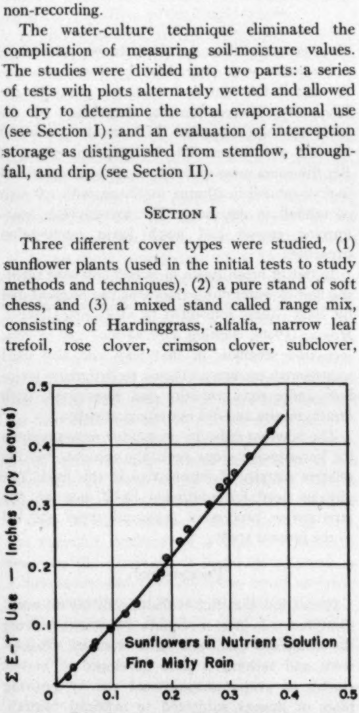

FIG. 1 – Accumulated evapotranspirational use, relationship of wet-leaf system to dry-leaf system, sunflower plants

FIG. 2 – View of grass plots on scales

Sunflower tests—Sunflower plants grown in nutrient solution, available from another experiment, were moved into pans and supported upright by submerged frogs. Plants in Pan A were wetted to drip point by a fine water spray. The water spread out over the surfaces with no tendency to form droplets. When the plants in Pan A were dry, the process was applied to the plant leaves in Pan B. The cycle could be repeated several times in one day, with automatic recording of the amount of water added and total amount of water used. Figure 1 shows the relationship of accumulated evapotranspirational use of wet-leaf systems to dry-leaf systems for 18 successive rainfall applications. These results are included here since they showed similar responses to the grass tests which followed.

Observe that, although moisture was retained by leaves and did evaporate, wetted leaves caused no excess water loss to the full system. In fact, the opposite is indicated: total usage was less for wetted plants.

Adding or subtracting small aliquots of water to or from the weighing pans indicated that much greater accuracy and reliability could be obtained with springless scales than from the spring-type rain-gage scales. Therefore, these scales were used for the remainder of the experiments (Fig. 2).

Hamilton and *Rowe* [1949] defined interception as "the process in which rainfall is caught by the vegetative canopy and redistributed as throughfall, stemflow and evaporation from the vegetation." This is a completely satisfactory definition. Interception storage can be defined as a depth of moisture that is retained on a given surface area. Interception storage accumulates, up to essentially a constant depth, as the rain continues, though it can be modified somewhat by winds and type of storm. This depth can then be termed 'interception storage capacity,' essentially the same value

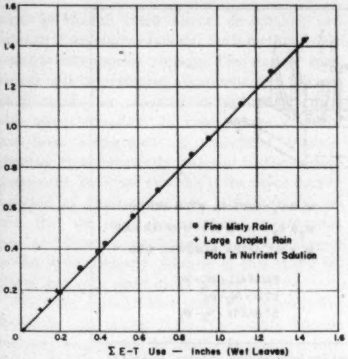

FIG. 3 – Accumulated evapotranspirational use, relationship of wet-leaf system to dry-leaf system, range-mix plots

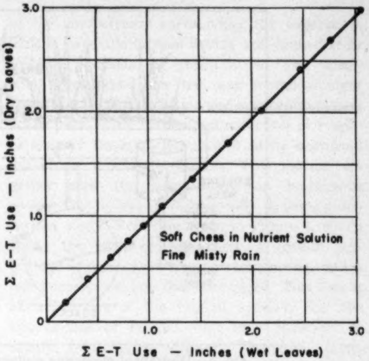

FIG. 4 – Accumulated evapotranspirational use, relationship of wet-leaf system to dry-leaf system, soft chess plots

as later will be termed 'gross interception loss.' From the results with sunflowers, 'interception loss' appeared to require re-defining into two terms: 'gross interception loss' and 'net interception loss.' Gross interception loss is "that portion of the rainfall that is retained on the aerial portion of the vegetation," which is part of the definition of interception loss as provided by Hamilton and Rowe. Net interception loss should be defined as that portion of the rainfall retained on the aerial portion of the vegetation that has no net effect on the soil water consumption of the plant. Net interception loss is the only truly lost moisture insofar as growing plants are concerned. In the trials where only growing and transpiring plants were used, net interception losses must be distinguished from interception storage. The following studies showed that no net interception loss occurred with grasses that were actively transpiring.

Range mix—The seed planted for the range mix trials produced a grass stand consisting principally of tall fescue and soft chess. For the data shown in Figure 3, cover density was nearly 100 pct, height of leaves ranged from about eight inches at the beginning of the trials, to about 16 inches at the end, three weeks later. Mowing the plots yielded an air-dry harvest of about 1500 lb/ac. All plants were apparently growing vigorously, and essentially similar in all four replicates. The systems were maintained in environments that were identical in wind movement, insolation, relative humidity, and temperature. The dense growth prevented rapid drying below the exposed, upper levels. Therefore, at least a full day was required for each trial. Whereas the sunflower leaves had wetted evenly, rainwater on the grasses collected as droplets. Figure 3 shows total water use as determined by the weight differentials of paired plots. Accumulated evapotranspirational use involved both misty rains and large-droplet rains, denoted by circles and crosses on the graphs. Here again note that no true loss of moisture occurred when the complete system is considered.

Soft chess—Figure 4 shows the results of trials of misty rain on a pure stand of soft chess. This grass stand was mature and extremely dense. Harvesting at the completion of the trials gave an air-dry yield of 4500 lb/ac. Lodging had choked and killed most of the center areas of each plot. Therefore, about ¼ to ⅓ of the canopy was not a transpiring cover.

SECTION II

Interception storage, stemflow, throughfall, and drip—*Horton* [1919] calculated the interception storage capacity of rye as 0.047 inch. *Musgrave* and *Norton* [1937] experimentally determined other interception values: corn, 0.145 inch; alfalfa, 0.140 inch; clover, 0.123 inch. These values gave no consideration to moisture flowing down the stems of the plants. *Grah* and *Wilson* [1944] determined an interception storage capacity of

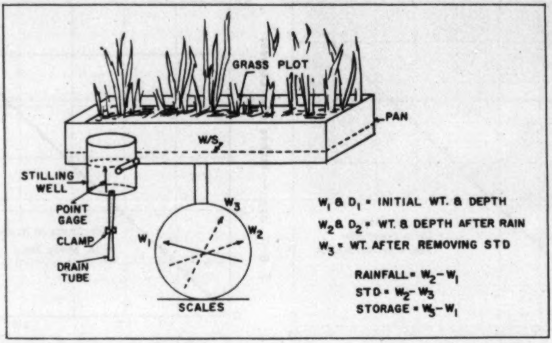

FIG. 5 – Diagram of measuring equipment for interception, storage, and STD

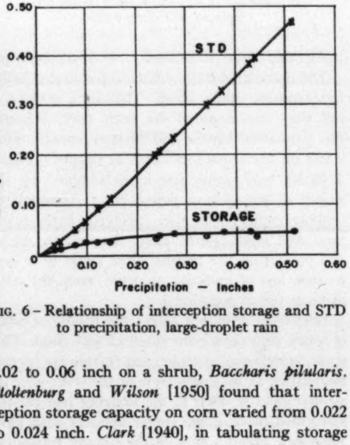

FIG. 6 – Relationship of interception storage and STD to precipitation, large-droplet rain

0.02 to 0.06 inch on a shrub, *Baccharis pilularis*. *Stoltenburg* and *Wilson* [1950] found that interception storage capacity on corn varied from 0.022 to 0.024 inch. *Clark* [1940], in tabulating storage capacities, reported interceptions varying from 1.21 inches on Big Bluestem (68 pct of 1.78 inches of rainfall), to 0.33 inch on slough grass (73 pct of 0.45 inch rainfall). His values seem exceptionally high. Clark stated that stemflow amounts were small, but it may be asked whether his method accurately assessed them on grasses.

In the present study no attempt was made to separate stemflow, throughfall, and drip (abbreviated STD herein) into components; they were assessed as a whole. The trials reported are for the range mix stands. The plots were representative of natural northern California rangeland cover insofar as the canopy was concerned. The grass was about ten inches high (therefore presenting less storage surface than may have been the case in previous investigations).

Method—Quantitative measurements of storage and STD were made by a slight modification of equipment and use of the same plant plots used in Section I. A stilling well with a submerged point gage was connected to one of the weighing pans. An initial depth of solution, at the crown of the plants, was established on the point gage. Rainfall was then applied to the system, after which the SDT water was removed to the original depth by extracting it through a hole in the bottom of the stilling well. This permitted both weight and volume determinations of the amount of water passing through the canopy as STD. The difference between final weight (after extraction of STD) and the original weight was the amount of storage on the leaves, expressed in inches over the area. Figure 5 diagrams this equipment. A check plot, on adjacent scales, provided values for consumptive use during the period.

Figure 6 shows the results of several STD and storage determinations. Transpirational uses were very low in most cases. It will be observed that storage accumulated up to values of 0.041 to 0.048 inch. It was possible to create an additional increment of storage, slightly over 0.01 inch, by applying more rainfall in a fine mist. This is not included in Figure 6.

DISCUSSION

Previous investigations of interception loss in the literature dealt almost entirely with differences in rainfall catch above, or outside, and beneath a vegetative canopy. Such methods only evaluate interception storage. The storage component will be evaluated accurately only in cases where means are provided to capture or otherwise assess stemflow. In cases where stemflow has been disregarded or considered inconsequential, it is incorrectly included in the storage component. In either case this is the value usually reported as interception loss. It appears, therefore, that the terms 'interception,' 'interception loss,' and 'interception storage' are often used more or less synonymously. Results of this study indicate that such usage is not proper.

The trials reported here show that interception obviously was taking place (the plants became wet) and evaporation followed (the plants dried). This could not be termed true interception loss, however, for when one considers total moisture use from the complete plant-soil-water complex, the use is effectively the same in both wetted and non-wetted systems.

Moisture could be lost in these trials by transpiration, evaporation from the nutrient solution, and evaporation of the intercepted 'rainfall.' Evaporation from the nutrient solution was very low, because of its shaded and protected location, and was essentially the same in all plots during any run. The distinguishing factor then becomes the moisture on the leaf surfaces. Although such moisture was evaporating from the leaves, a like reduction of transpiration was effected, as indicated by these results.

Several past workers, *Christiansen* [1942] and others, reporting on sprinkler investigations have recognized this and have supposed a reduction of transpiration when leaf surfaces were wetted. *Harrold* and *Dreibelbis* [1951] approached this same conclusion when they reported that dewfall or rain in the night conserved soil moisture the following day. The plants in the lysimeters were wet at the beginning of the day.

Under any evaporative conditions, wet leaves transpire less water than do dry leaves. Since grass leaves do not actually wet, but merely retain water droplets, the coverage is not uniform. Therefore, the energy available for evapotranspiration on wet leaf areas is used to vaporize free water from the droplets, in contrast with a continuing normal (or nearly normal) transpiration rate from the dry areas of the leaves. The reduction of transpiration is related to the decrease in vapor-pressure gradient from leaf stomata to atmosphere that is occasioned by the increased vapor content of the microclimate surrounding the vegetation. This is particularly true during and immediately following periods of precipitation. The somewhat special condition that may prevail at night with regard to transpiration and interception losses is complicated by an unequal reduction of evaporation and transpiration as well as by nocturnal variations in climatic factors. This matter, together with the relationships on herbaceous species that do wet more uniformly, is being given further study. Referring again to Figure 4, which shows the trials on soft chess, a certain percentage of this cover was non-transpiring, and a net interception loss did take place. This loss is about 15 pct of the rainfall applied. But the applications of rainfall were only sufficient to satisfy interception storage. Therefore, interception loss was 15 pct of the interception storage capacity, or about 0.0075 inch in the period. As has been noted previously, these plots contained a considerable percentage of dead grass. Intercepted moisture on such dead surfaces evaporated, whereas transpirational losses from such dead surfaces did not occur. Therefore a net interception loss to the system took place. This leads to the conclusion that the whole complex of surfaces, living and dead, transpiring and non-transpiring, maximum transpirational use and less than maximum transpirational use, must be considered in discussing interception losses for grasses or in fact any plant cover. This complex could be affected by season of the year, type and condition of plants, management of cover, and even the time of day. Further work is planned to investigate these factors.

SUMMARY AND CONCLUSIONS

Methods and equipment were devised to study the interception process in grasses. Tests on small, growing grass plots showed that the entire plant-soil-water-rainfall complex must be considered in evaluating the net effect of this intercepting canopy on precipitation disposal.

On transpiring grasses under rainfall such losses as may occur from the aerial part of the plant are accompanied by an equal reduction of moisture use from the 'soil.' When a portion of the grassy vegetation is dead, a net interception loss is observed. This loss amounts to some percentage of the storage capacity of the vegetation. The magnitude of the net loss seems to be related to the ratio of non-transpiring to transpiring surfaces.

Increases of water yield following conversion from brush to grass, mentioned earlier, are supported by the results of this study. Part of this increase is due directly to lower net interception loss from grasses. The influences of grass cover on soil condition, infiltration and hydraulics of overland flow are also important considerations.

Results show that the interception storage capacity of a grassy canopy is not satisfied by a rainfall equal to this storage capacity. Rather, storage is satisfied in increments as the rainfall progresses, so that a large portion of the rain reaches the ground even at the beginning of small storms.

It seems desirable to re-examine the terminology heretofore used in interception studies, bearing in mind the necessity for considering the complete system. The storage capacity of the plant does not necessarily represent the magnitude of net interception loss.

Shallow Ground Water and Tile Drainage in the Oxnard Plain

J. D. ISHERWOOD AND A. F. PILLSBURY

Abstract—A study of the hydrology of the shallow ground waters of the Oxnard Plain, Ventura County, California, was made using a network of piezometers at 10 and 20 ft below the surface. Mean depth to water is 6.8 ft and shows little difference between January and June readings during the years 1953–1956. The perched water table slopes to the south and southwest. It is only slightly above sea level near the coast. Piezometric head differences established the presence of a downward gradient over most of the area. The shape and rate of recession of the water table in tile-drained land and tile effluent rate were measured at various sites. Twenty-two per cent of water applied is discharged from tile lines as waste. Equipment and technique for hydraulic conductivity measurement in unstable soils is described.

Introduction—Field investigations were carried out on the Oxnard Plain, in the southwest portion of Ventura County, California. This is a rather low-lying area adjacent to the coast, originally saline, reclaimed by drainage with subsequent leaching. (It is understood that a large measure of the success of drainage in this area belongs to Walter W. Weir, Drainage Engineer, Emeritus, of the University of California, who gave considerable expert advice to local people planning the works.) It now supports a highly productive agriculture, notable products being lemons, lima beans, and off-season vegetables. Studies were confined to the area south of the Santa Clara River and west of Calleguas Creek. These are the two main drainage channels of the plain, and run approximately west and south respectively. They discharge into the Pacific Ocean which forms the western boundary.

Annual rainfall averages about 14 inches but was below normal during two years of this investigation. Drainage from the area is accomplished by means of an extensive system of tile drains and a relatively small number of open ditches (Fig. 1). Farm ditches are being replaced gradually by collector lines. Ditch maintenance, weed control, and the loss of valuable land are thus eliminated. The lateral tile lines usually discharge into collection lines from which the water flows to the district ditch system, thence to the ocean via one of the main drainage channels. Very few individual laterals suitable for effluent measurement were found discharging directly into ditches.

Objectives of the investigation were (a) to make a general survey of the area to determine the facilities that had been required to create a highly productive agriculture on land previously almost worthless; (b) to evaluate the shallow semi-perched ground-water levels resulting from the drainage measures utilized; and (c) to study the mechanics of the movement of ground water to the tile drains to provide more rational design criteria.

Soils and stratigraphy—Soils in the Oxnard area are recent alluvium from sedimentary rocks and old valley fill material which have been transported and deposited by the Santa Clara River. The majority are classified as Yolo with a few areas in the Dublin series. The surface soils are generally fairly homogeneous to a depth of six to eight feet and generally overlie much less permeable silts and clays. This subsoil material was laid down on the flood plain by the Santa Clara River and there is little continuity to the strata. Deposits typical of flood plain deposition are found ranging from fine gravel through sands, silts, and clays, at depths between 10 and 20 ft below the surface. Auger-hole samples were taken down to 16 ft at the three major tile-line investigation sites, but mechanical analyses did not indicate the presence of a true clay. From information gathered from local farmers, it appears that an impermeable barrier does underlie parts of the plain. The shallowest depth reported was 14 ft below the surface. Stratigraphic information obtained while jetting in piezometers to 20 ft below the ground surface indicated no continuous clay layer, but rather a series of clay and silt lenses of low permeability which were interspersed with lenticular deposits of fine sand, coarse sand, and fine gravel of high permeability. South of Highway 101 between Rice and Las Posas Roads, a series of piezometers jetted to 30 ft indicated that similar conditions prevailed between 20 and 30 ft with sand layers constituting in some cases more than half of that 10-ft interval. No thick clay layers were present down to 60 ft at field Site 3.

The lenticular silts and clays provide an ef-

fective local barrier, however. Piezometric head measured at points 14 and 20 ft below the surface often showed a high downward gradient (up to five feet of difference in piezometric head at the two points or a gradient of more than 0.8). Such data substantiate the existence of low vertical permeability between the 14- and the 20-ft level at those locations. On the other hand differences of piezometric head were small in areas where sands occurred between the depths at which the head was measured.

The ground surface slopes gently and uniformly to the southwest, with elevations ranging from 100 ft inland to almost sea level along the coast.

Water-table survey—Little information was available on the hydrology of the shallow ground water. Previous surveys [*California Division of Water Resources*, 1933, and 1953; *U. S. Department of Agriculture*, 1920] have shown that the Oxnard Plain overlies pressure aquifers which were still flowing from water-supply wells some 20 years ago. The presence of artesian water clearly indicates a flow barrier between the deeper aquifer and the surface, which is borne out by the existence of a shallow perched water table a few feet below the ground surface. Water levels in wells penetrating the Oxnard aquifer have now dropped to below sea level. Figure 2 shows the locations of 140 ⅜-inch diameter piezometers 11 ft long which were installed on roughly a half-mile grid over the area, to obtain shallow ground-water elevations.

The network was read in January and June of each year beginning in January 1953. Readings were taken using an electrical sounder [*Donnan* and *Bradshaw*, 1952] and plotted on a map showing water-table elevations above sea level and depth to water below ground surface (Fig. 3). Water-table elevations determined in this manner show a positive seaward gradient at all points. At no time since the beginning of the survey has the ground-water level fallen below sea level although piezometers near the coast show only a slight positive elevation. Ground-water movement, in general, follows the main surface drains, Revlon Slough and Calleguas Creek, and flows in a southerly direction to the coast.

Deep percolation—The usefulness of piezometers to different lengths at the same location to determine vertical gradients has been firmly established in other areas [*Reger* and others, 1950]. A network of 21-ft piezometers on approximately a one-mile grid was installed by jetting as described by *Pillsbury* and *Christiansen* [1947]. These piezometers were located within a foot or two of the 11-ft piezometers already installed (Fig. 2). To penetrate some of the coarse sands encountered, a commercial drilling mud preparation (Aquagel) was added to the jetting water at a rate of 10 lb per 100 gallons of water. Without the Aquagel these sands are so highly permeable that none of the flow of water from the jetting pipe returns to the surface, and progress is impossible. After flushing with clean water, piezometers installed in this manner responded normally to changes in the piezometric head.

Readings of both 21-ft and 11-ft piezometers were taken at six-month intervals in 1953, 1954, and 1955. These data show a definite downward gradient over the entire plain with a mean value of 0.05. Site 3 showed mean downward gradients during 1954 of 0.11, 0.1, 0.1, 0.14, and 0.18 over the intervals 7–12, 12–15, 15–21, 21–27, and 27–63 ft respectively. Time did not allow a complete water balance to estimate deep percolation losses over the plain but a very rough approximation was made by measuring the change in water level in two piezometers during a summer period when no irrigation water was applied in the vicinity. The water levels were well below the neighboring tile drains and slightly above the bottom of the nearest ditch (¼ mile distant). If no lateral movement occurs, the drop in water level may be attributed to downward movement into deeper zones. Below the fairly non-stratified surface soil the particular nature of the profile makes it unlikely that the mean hydraulic conductivity in a horizontal direction will be any greater than in a vertical direction. In any case the influence of a drainage ditch is somewhat localized, so that the rate of water-table recession at a point ¼ mile from a ditch is likely to be low. The horizontal gradient is extremely small. In one case the piezometer water level was two feet above the ditch water surface ¼ mile distant; in the second case seven feet in ¾ mile which are gradients of 0.0015 and 0.0018. Vertical gradients vary from 0.15 to 0.30 depending on the elevation of the perched surface (assuming the mean depth of the Oxnard aquifer to be 200 ft.).

The assumption made above regarding the likely equality of horizontal and vertical hydraulic conductivity may be incorrect; but even if the horizontal conductivity exceeds the vertical by 100:1, the horizontal gradient would still hardly exceed the vertical gradient.

To interpret the change in water level in the soil in terms of true water quantity the specific yield was determined from 36 core samples taken from a depth of five feet. Moisture content at ⅓ atmosphere (assumed equivalent to field capacity) and bulk density were determined. The mean specific yield of 16.1 pct shows remarkable agreement with the 16 pct found by the State Division of Water Resources for the deeper aquifer.

The two piezometers observed both gave, perhaps fortuitously, a change in level equivalent to 0.9 ft of water per year. At the very least one-half of this or 0.45 ft/yr may be attributed to deep percolation and it is possible that all 0.9 ft percolates through to the deeper zones. The total extent of the area covered by this study is around 32,000 ac, which means an annual recharge to the deeper zones of 14,000 ac ft of water (using the conservative figure of 0.45 ft). This is a significant amount when the annual pumping draft is considered to average 1½ to 2 ft, or at maximum 64,000 ac ft per annum. Almost one-quarter of the annual draft may actually be replenished by deep percolation. The quality of the shallow water is poor. Mean electrical conductivity (EC) from 20 samples was six millimhos/cm. To give some idea of the original salinity status of this area note that on land that was tiled during the course of the investigation, the EC of the tile effluent was 46 millimhos/cm after the third leaching.

Tile-drain performance—Three locations were chosen for tile-drain investigation (Sites 1, 2, and 3, Fig. 2) and measurements of effluent rate, cumulative discharge, hydraulic conductivity, and water-table recession following irrigation were made at each site. Originally measurements following rainfall were expected to provide some reliable information. Natural precipitation tends to be more uniform than irrigation, and the quantity of water applied is easily calculable from rain gage figures. Unfortunately, the only rainfall of sufficient intensity or duration to raise the water table appreciably also raised the drainage ditch level above the lower end of the tile drain. Investigation of drainage characteristics of tile lines were therefore confined to the summer irrigation season. Three tile lines were selected and the outlets equipped with tipping buckets. Plots of the effluent rate versus time are shown in Figure 4 for Sites 1 and 3. The initial rates are not maximum for these tile systems since effluent data with the soil saturated to the surface were impossible to obtain.

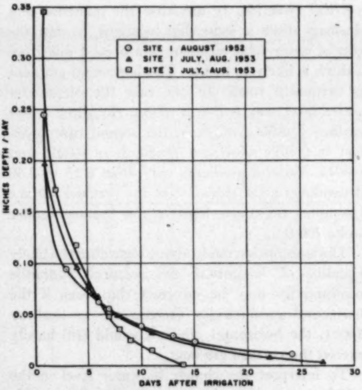

FIG. 4 – Tile discharge rates

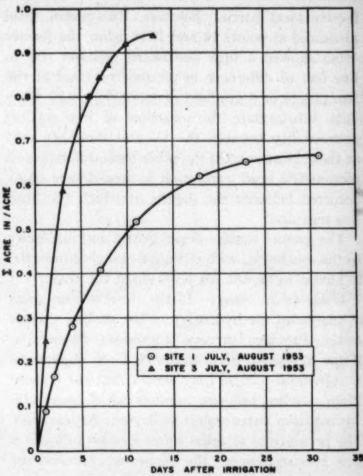

FIG. 5 – Cumulative tile discharge

Cumulative discharge—Figure 5 shows the cumulative discharge at Site 1 and Site 3 in 1953. The 1952 records of Site 3 are meaningless because the title line was found to be partially plugged with eucalyptus roots. On the other hand, in 1953 with a normal irrigation cycle, there was no flow before irrigation and measurements were made until flow again ceased. The irrigation was light, the water table rose to a maximum of 0.15 ft above the top of the tile and yet 27 pct of the water applied

was ultimately discharged to the ditch as waste.

Total cumulative discharge figures for three irrigations were 0.66, 0.94, and 0.96 acre inch per acre. Including drainage directly into ditches 1.0 acre inch per acre would appear to be a representative figure for the quantity of excess leaching water applied per irrigation. The annual pumping draft is 18 inches which means that, assuming four irrigations per year, $\frac{4}{18}$ or 22 pct of applied water is ultimately discharged as waste. The U. S. Salinity Laboratory method of computing leaching requirement, using the ratio of the EC of water applied to that of the drain effluent, yields 1.4/6.0 or 23 pct. It appears that on the basis of the above calculation the amount of leaching water used is not excessive. Approximately half of the total effluent is discharged in the first $\frac{1}{8}$ of the flow period. However, a detailed study of salt balance in this area might lead to a reduction in the presently excessive pumping draft on the deeper artesian aquifers.

Water-table recession—Piezometer readings on the recession of the water table following irrigation were made at all locations. Piezometers of three different lengths were originally installed at each point but gave identical readings in the shallow zone down to the tile line. Thereafter a row of single piezometers on one side of the tile was used with an electrical sounder to establish water levels. Figure 6 shows examples of the type of recession curves obtained. One feature which attracts immediate attention is the very rapid drawdown over the tile line. In one set of readings indeed the water table at the midpoint stood almost eight feet above the top of the tile line, while the piezometer inserted at the tile line indicated no water above the tile at this point. A disturbance of the

original stratification in the trench dug to lay the tile line can lead to this type of recession curve. In this particular case it was difficult to confirm this by soil samples although a clay layer at a depth of five to seven feet close to the tile line was not present above the line. However, the same layer did not occur at the midpoint between lines either. It would appear that anisotropy or stratification, although not continuous, is sufficiently pronounced in this locality to make the trench effect quite apparent.

In all four recession rate plots the various stages in the recession of the water table are far from being parallel. The fall at midpoint is in all cases considerably greater than the fall near the tile itself. Clearly the succession of nearly parallel water surfaces as found by *Childs* [1947] is missing and will in practice never be present with drain spacings of this order (200 ft). For a 200-ft spacing the stages would no longer be parallel when the water-table height at the midpoint is less than about 25 ft above a drain [*Childs*, 1947, Fig. 3]. Drains are not laid at such depths and consequently the parallel surface stage is absent. The relationships between the surfaces in this nonparallel region are consequently the ones of major practical interest, and more particularly at the midpoint between drains where the water table will be highest.

Plots of midpoint height of water table above drain tile invert yielded a simple exponential function which was further confirmed by subsequent midpoint water-level readings in various locations as shown in Figure 7. The electric analogue results obtained by *Childs* [1947] and some unpublished data by *Klinge* [1955] are plotted in Figure 8.

If this exponential relation between water-table height and time is extrapolated, the time for the water table to fall one foot from the surface may be computed from

$$\log H - \log (H - 1) = cT \qquad (1)$$

where H is the depth in feet of the tile invert below the ground surface, T is the time in days, and c is the slope of the curve. The results are shown in Table 1. It is interesting to note that for Sites 1 and 2 the computed recession rate from the surface is close to one foot in two days as suggested by *Neal* [1934].

Hydraulic-conductivity measurements—Preference was given to *in-situ* methods (the auger-hole and the piezometer methods) for the determination of hydraulic conductivity. A few trial borings with a 2-inch auger indicated that open-hole methods were not feasible in the Oxnard area. A technique was, therefore, necessary to install a screened test hole in these unstable soils. Moreover the method had to be adaptable to measurements with the water table below five feet. The ground water is rarely closer to the surface except immediately following an irrigation or heavy rainfall.

The test borings indicated that continuous casing of the hole below the water table would be essential. This was achieved by jetting in a 2-inch diameter electrical conduit casing. After removing the jetting pipe one of the screen arrangements, shown in Figure 9 for the auger-hole or the piezometer method, was lowered into the conduit, which was then raised to a stop on the $\frac{3}{4}$-inch pipe attached to the screen.

The water table was allowed to stabilize and the static level read from an electrical sounder. With the short 4-inch screen the sounder wire was run in the annular space between the $\frac{3}{4}$-inch pipe and the 2-inch conduit. In the long screen the sounder wire was inside a $\frac{1}{4}$-inch diameter pipe. The $\frac{1}{4}$-inch pipe was included in the long-screen equipment since it enabled the water level to be lowered almost to the bottom of the screen. This was felt to be unnecessary with the short screen. Apart from this, installation and measurement techniques for both methods are identical. The rate at which the water level builds up is timed and the hydraulic conductivity determined from equations derived by *Kirkham* [1948, 1949], allowance being made for the screen and pipe volumes.

Hydraulic-conductivity measurements were made with this equipment at Sites 1 and 2 and later at Sites 4 and 5. At Site 3, the water table was not high enough above the tile line to allow a comparison with the other tile systems. Results are shown in Table 2.

Now it is reasonable to assume that, other conditions remaining the same, the rate of drop of the water table at the midpoint will vary directly as the hydraulic conductivity K, and inversely as the drainable pore space f. Comparison of the last two columns of Table 3 clearly indicates that the field measurements fail to support this assumption.

In most aspects, all four sites are comparable. Each spacing is 200 ft. Drainable pore space f has only a limited range of values, even with 100 pct error in measurements. Any error in barrier depth is similarly limited. The major variable of unlimited range is hydraulic conductivity itself. To obtain a reliable value of hydraulic conductivity, a large number of measurements must be made, even in a relatively homogeneous soil. Spot measurements in shallow homogeneous soils, where hydraulic conductivity can be determined down to the barrier layer, may give the desired information with some assurance. The Oxnard soils, somewhat typical of the deep alluviums of southwestern United States requiring deep drainage, are far from homogeneous below the tile drains. They tend to be characterized by discontinuous stratification and marked anisotropic properties. *Van Deemter* [1950] has indicated that for soils with no effective barrier layer in the profile, the majority of the flow occurs in a region of depth S/4 where S is tile line spacing. It is quite impractical to obtain hydraulic conductivity of soil to 50 ft depth (S/4 for the common 200-ft spacing). Even with elaborate field equipment and power tools, as used in this work, field determinations by a few spot tests are prohibitive in cost, and clearly a great number of such tests would be required for significant results. Spot methods for hydraulic-conductivity determinations obviously have no merit here. The eventual resolution of this problem may come from the application of geophysical techniques. For the immediate future, a solution based on the recession rate midway between two widely spaced tile drains appears to hold some promise.

To attempt to correlate the recession rate with hydraulic conductivity and clay depth would involve an extensive field program. Preliminary investigations at various points indicated that neither visual inspection nor mechanical analysis were satisfactory to establish accurately the depth of an impermeable barrier. Moreover, the number of hydraulic conductivity measurements would be prohibitively large to attain even a fair degree of accuracy. Additional work using a mathematical model to investigate the relationship between the rate of recession and the parameters influencing this rate is in progress.

Acknowledgments—This research was a part of Project H-1539 LA. The authors wish to express their appreciation to Robert E. Pelishek for his able assistance in carrying out the field program.

On the Measurement of the Thermal Conductivities of Rocks by Observations on a Divided Bar Apparatus

ALAN E. BECK AND JULIA M. BECK

Abstract—Rapid techniques for the preparation of disks of rock and for the determination of rock conductivities have been used to make a large number of measurements on both coarse-grained and fine-grained rocks. Methods in which either sets of disks or single disks can be used are described and the mean values of conductivity found by combining the results in various ways are compared. The modes of the rocks were found by examination of thin sections for the fine-grained rocks and by examination of each disk for the coarse-grained rocks. Conductivities computed from the modes by the method of Birch and Clark are compared with the experimentally determined conductivities. The significance of rock structure in the selection of representative specimens and the effect of moisture content in porous rocks is discussed. The work indicates that, at least for the coarse-grained rocks, the usefulness of the conductivities obtained from divided bar measurements can be seriously questioned, and that the usual methods of saturating porous rocks are not wholly satisfactory.

Introduction—There is a steadily increasing interest in the flow of heat from the crust of the Earth, both from the land masses and from the bottoms of the oceans. It is the belief of the authors that the greatest need in this work is for a large number of results from all over the Earth. If these results are plotted on a world map and lines of equal heat flux, better described as isoflux lines, are drawn, a general picture of the pattern of terrestrial heat flow may appear.

In any area the calculation of the flow of heat requires a knowledge of the local temperature gradient in the crust and of the thermal conductivity of the rocks in the region; the measurement of the temperature gradient by electrical methods is reasonably rapid and straight forward, but most of the methods of determining the conductivity of rocks involve tedious and complicated procedures. It is the object of this paper to show how it is possible, with suitable apparatus and techniques, to increase the speed and accuracy with which conductivities can be determined and to underline some of the difficulties which up to now appear to have been too lightly treated.

A divided-bar apparatus, capable of reaching the steady state within ten minutes of a specimen being introduced between the bars, was used to find the conductivities of the rocks; a detailed description of the apparatus has been given elsewhere [*Beck*, 1957]. Briefly, however, the method consists of introducing a disk of rock between two vertical cylindrical brass bars; the top end of the upper bar is heated with water controlled thermostatically at 36°C while the bottom end of the lower bar is cooled with water controlled thermostatically at 19°C. The thermal conductivity of the specimen is determined in terms of the conductivity of the bars from temperature measurements made along the bars after the steady state has been reached. The thermal contact resistance between the bars and the specimen is found and eliminated by measurements with three or more disks of different thicknesses. Details of a new method of rapidly cutting off disks of rock will be published elsewhere.

Throughout the paper the units are cgs, °C, and cal except where otherwise stated.

Descriptions of specimens—The scientific value of measured conductivities of rocks is greatly increased if they are accompanied by a statement of their mineral composition and structural features. Furthermore, a knowledge of the quantitative composition is valuable since a theoretical value of the thermal conductivity of the rock may be calculated from it. This method of determining the conductivity is discussed in later sections of the paper and results are compared with those obtained from laboratory methods.

Table 1 lists the mineral composition of rocks from three boreholes in the Snowy Mountains area of New South Wales, Australia. The mode of fine-grained rocks was found by the usual method of examining slides with the aid of an integrating stage. For coarse-grained rocks, in which the conductivity of contiguous disks may differ by as much as 50 pct, it was necessary to find the mode of each disk since the mode of a slide, although more accurately determined, may bear little relation to the mode of the disk. The disk was examined under a binocular microscope with a 100 square

S—Mineral composition was determined from a slide.

[a] Mineral composition was only estimated under a microscope; all other compositions were accurately determined.

grid in one eyepiece and, for each major mineral, measurements were made of the total length of intercept along parallel lines of the grid; this was done for both sides of the disk and the mean taken. The area of observation corresponded with the area enclosed within the guard ring of the divided bar apparatus [*Beck*, 1957]. By coating the surface of the disk with oil, felspar, mica, and quartz could usually be readily differentiated, though in places where the felspar was fresh, difficulty was experienced in detecting the junction between quartz and felspar. To estimate the error in computed conductivities likely to arise from this cause a troublesome specimen (50 from Hole 1) was measured twice. In one case all the doubtful material was classed as felspar and in the other case it was classed as quartz; the resultant difference in computed conductivity was 10 pct. Both values are shown in Tables 1 and 2.

The compositions of rocks from Hole 3, as shown in Table 1, are only approximate. Many of these rocks are very fine grained and altered and the mode was estimated from the examination of slides without making any systematic measurements. Clearly the conductivities computed from these figures are less reliable than those calculated for rocks from the other holes.

Hole 1—In hand specimen it was only possible to divide the rocks from this hole into aplites, which were recorded in the drillers' logs as dykes, and granites which appeared to be very uniform. However, in thin section it was found that some of the rocks described as aplites contained significant amounts of biotite and therefore could be more accurately called microgranites and microgranodiorites; the coarse-grained rocks showed distinct variations in the proportions of quartz, orthoclase, and plagioclase and so could be divided into granites, adamellites, granodiorites and quartz monzonites. These distinctions, based mainly on relative amounts of orthoclase and plagioclase which have very similar thermal conductivities [*Birch* and *Clark*, 1940], would have little effect on the conductivity of the rock and therefore are not shown in Table 2.

Hole 2—This hole passed mainly through fine-grained quartz diorites; in places lamprophyres, presumably forming dykes, and xenoliths of porphyrite were intersected. In Table 2 the grain size refers to the original size of the primary minerals; it is always much greater than the present average grain size of the rock because in most specimens more than half the plagioclase has been strongly saussuritised and the biotite and hornblende have been partly altered to chlorite.

Hole 3—Fine-grained granites, dolerites, and

MMX Medium section of biotite xenolith through specimen.
SSX Small section of biotite xenolith through specimen.
[a] Rocks named from examination of slides and reference to drillers logs.
[b] Indicates that mineral composition has been accurately determined and is given in Table 1.
[c] Indicates that mineral composition has only been estimated and is given in Table 1.
Subscript s denotes conductivity computed assuming a series arrangement of minerals; all other computed conductivities are found assuming a parallel arrangement of minerals; 1 and 2 are different thin sections of the same rock.

porphyritic microgranites were intersected by this borehole. As noted earlier most of them have been altered, either by weathering, shearing, or pneumatolysis, including strong greisenisation, and their compositions have been determined only approximately.

Conductivities obtained from sets of three or more disks—Between the faces of the specimens and the bars of any divided bar apparatus there is a thermal contact resistance which is found and eliminated by measurements on three or more disks of different thicknesses cut from the same rock. To do this the total thermal resistance, including the contact resistance, of each specimen is plotted against its thickness D in cm. A straight line is obtained of the form

$$\Theta \Big/ \frac{d\theta}{dx} = B + \frac{k_1}{k_2} D \qquad (1)$$

where Θ is the temperature difference between the two faces of the brass bars, $\frac{d\theta}{dx}$ is the temperature gradient in the brass bars, B is the sum of the thermal resistances of the two interface films and k_1 and k_2 are the conductivities of the brass and rock respectively. If the conductivity of the brass is known the conductivity of the rock can be found from the slope of the line; the intercept at $D = 0$ will give the contact resistance B. In this work the equation of the straight line and the standard deviation of its slope have been found from the least squares theory.

The conductivities of sets of specimens from three boreholes are shown in the third column of Table 2. When a set of disks gave a value of conductivity with a standard deviation greater than 3 pct the complete set was measured again. In no case did the second value for the total thermal resistance of an individual disk depart from the original value by more than 1 pct and the standard deviation of the set did not change by more than 0.6 pct; the comparatively large standard deviations of many of the sets of disks therefore indicate real variations of conductivity from disk to disk.

Errors which may arise when the thermal conductivity is derived from a set of disks are demonstrated by omitting certain disks from the set and calculating a new least-squares straight line through the thermal resistance-thickness points; it can be seen (Hole 1, 100 ft; Hole 3, 248 ft) that markedly different values for the conductivity can be obtained. In another case (Hole 3, 394 ft) the conductivity is not significantly altered but a completely erroneous idea of the accuracy is obtained.

The use of single disks—With a little skill extremely uniform disks can be produced; it might therefore be hoped that, at least when a liquid contact film is used, the contact resistance would vary so little from disk to disk that a standard contact resistance could be found for a given instrument and tolerances of rock machining. This resistance could then be used with a single disk to give a measurement of conductivity. This practice would have the effect of decreasing to at most one third the time involved in preparing specimens; it would also be of great advantage with the many friable and broken rocks from which it is not possible to get a set of three disks, and with other rocks, particularly with some schists, from which it is frequently impossible to cut thin disks at all. A further disadvantage of the standard procedure when applied to coarse grained rocks will appear below.

To determine whether it was possible to use a standard resistance a histogram (see Fig. 1) was plotted of all contact resistances obtained. This histogram has a mode at about 0.5 cm brass and includes the many aberrant values, both negative and high positive, which were measured. (It is convenient in practice to express contact resistance in cm of brass. This unit is used throughout this work. To convert to the usual units, sec cm °C/cal, multiply by 4.3.) These, which have been noted elsewhere [*Bullard*, 1939], occur in coarse-grained rocks in which the normal laboratory disks are not representative of the rock as a whole, and are brought about by a scatter of points when the total thermal resistance is plotted against the disk thickness. This scatter of points, which indicates a difference in thermal resistance per unit thickness, is due to (1) the high probability of finding, from disk to disk, a variation in the proportions of the constituent minerals; and (2) an increasing probability, as the disk thickness increases, of the disk having a 'series' arrangement of minerals. The question of 'series' and 'parallel' arrangements of minerals is discussed subsequently.

To obtain a more accurate standard contact re-

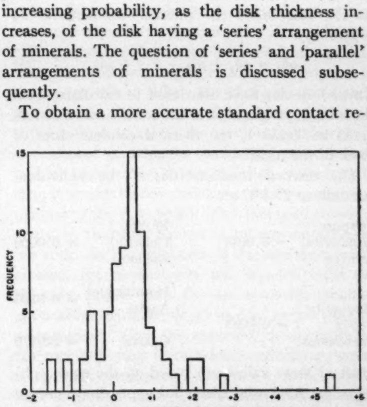

FIG. 1 – Histogram of contact resistances for 82 sets of disks

sistance only those lines of positive intercept and with a standard deviation of 1.5 pct or less were used; this effectively sets a limit on the curvature caused by the effects mentioned above. The mean value found by this method was 0.49 cm ± 12.2 pct. Since the average thermal resistance of a disk of rock 2 mm thick was about ten times the contact resistance (that is, from Eq. (1), $0.2\ k_1/k_2 \approx 10\ B$) an error of 20 pct in the contact resistance will give only 2 pct error in the thermal resistance of the 2 mm disk and less for the thicker ones. The conductivities found by subtraction of the standard contact resistance from the measured total resistance of each disk are shown in the seventh column of Table 2. The thickness of the specimens is given to the nearest 0.5 mm. The figures in the columns marked 'computed' are based on the mineral compositions given in Table 1 and are discussed in the following sections.

Thermal conductivity computed from the volume percentage of the constituent minerals—The idea of 'series' or 'parallel' arrangements of minerals was introduced by *Birch* and *Clark* [1940]; it is developed later but it may briefly be stated here that if a rock consists of n minerals with α parts of a mineral of conductivity k_a, β parts of a mineral of conductivity k_b, $\cdots$, η parts of a mineral of conductivity k_n, then its 'series' conductivity k_s is given by

$$\frac{n}{k_s} = \frac{\alpha}{k_a} + \frac{\beta}{k_b} + \cdots + \frac{\eta}{k_r} \qquad (2)$$

on the other hand the 'parallel' conductivity k_p is given by

$$nk_p = \alpha k_a + \beta k_b + \cdots + \eta k_n \qquad (3)$$

These formulas have been used to calculate, from the volume proportions of the constituent minerals given in Table 1, the thermal conductivities of some of the rocks.

The thermal conductivities of the individual minerals at 27.5°C are

$$\left.\begin{array}{l}\text{Felspars}\\ \text{Muscovite}\\ \text{Sericite}\end{array}\right\} = 0.0045 \qquad \left.\begin{array}{l}\text{Biotite}\\ \text{Chlorite}\\ \text{Epidote}\end{array}\right\} = 0.0060$$

$$\left.\begin{array}{l}\text{Hornblende}\\ \text{Augite}\end{array}\right\} = 0.0100$$

$$\left.\begin{array}{l}\text{Magnetite}\\ \text{Topaz}\\ \text{Carbonates}\end{array}\right\} = 0.0085 \qquad \text{Quartz} = 0.0170$$

Most of these values are based on the work published by Birch and Clark but approximations are used in those cases for which they give no definite figure. In this respect, the only mineral of any significance is biotite. Birch and Clark did not measure the conductivity but tentatively estimated its value as 0.01. However, in many of the rocks used in the present work some of the biotite has been altered to chlorite the conductivity of which is 0.0060 [*Mossop* and *Gafner*, 1951]; the type of replacement and the broadly similar structure of the two minerals suggested that a fairer picture would be given by assigning this value to the biotite. The fact that the conductivity of specimens from the 35-ft level of Hole 1 decreases as the volume occupied by the biotite xenolith increases, supports the validity of this lower value.

The results of the computations are shown in the eighth and ninth columns of Table 2. The values with the subscript s are the series conductivities; the others are the parallel conductivities. The values in the eighth column were obtained from measurements on the actual disks used while the figures in the ninth column were derived from the mode of the slide.

Mean value of thermal conductivity—Comparison of the figures in the third and seventh columns of Table 2 shows up the limitations of the method of using three or more disks in the divided-bar apparatus. In particular it may be noted that conductivities of 0.0075 and 0.0081 were obtained from two separate sets of disks cut from the core from the 100-ft level of Hole 1. More than 450 ft of this hole passes through granite of very uniform composition but the measured values of the thermal conductivity of individual disks range from 0.0066 to 0.0107 (col. 7, Table 2). These variations are brought about by the reasons given in the section on single disks and are most probably fluctuations about a mean. There were 48 disks of this granite and it is worth while, therefore, comparing values of the mean conductivity obtained from the procedures described in the previous sections. The four main methods of treating the data are as follows:

(1) Using the values derived from sets of three or more disks.

(2) Plotting on one graph all total resistances against thickness, regardless of depth, and calculating the least-squares straight line for all points (Fig. 2). When this was done and the residuals (observed resistance − calculated resistance) were arranged in order of depth it was noticed that the majority of the residuals from 0 to 142 ft. were positive while below this the majority were negative. As this indicates a difference in thermal conductivity the points were divided into ranges and two new straight lines determined.

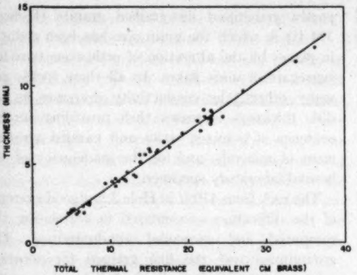

FIG. 2 – Least-squares straight line through points for 48 disks of a fresh coarse-grained granite

(3) Using the values obtained by determining a value for the thermal conductivity of each disk assuming a standard contact resistance of 0.49 cm of brass.

(4) Using the computed parallel conductivity of each disk.

The results from these methods are compared in Table 3; standard deviations are also shown.

TABLE 3 – *Mean values for conductivity of coarse-grained granites in Hole 1*

Method	Remarks	Conductivity
		cal/cm sec °C
1a	Unweighted mean from straight lines	0.0083 ± 3.4 pct
b	Weighted mean [*Birge*, 1932] from straight lines	0.0082 ± 1.1 pct
2a	Plotting all total resistances against thickness	0.0080 ± 2.1 pct
b	Dividing into two ranges	
	0 to 142 ft.	0.0079 ± 2.4 pct
	142 to 465 ft.	0.0082 ± 3.6 pct
3a	Subtracting contact resistance of 0.49 cm brass from the total resistance	0.0086 ± 1.3 pct
b	Dividing into two ranges	
	0 to 142 ft.	0.0083 ± 1.3 pct
	142 to 465 ft.	0.0088 ± 1.7 pct
4a	Computed conductivity for all specimens	0.0085 ± 1.8 pct
b	Dividing into two ranges	
	0 to 142 ft.	0.0083 ± 2.3 pct
	142 to 465 ft.	0.0087 ± 1.4 pct

For some of the disks the computed conductivity assuming a parallel arrangement of minerals differs appreciably from the measured conductivity Table 2, but the errors (observed value – computed value) follow a normal distribution, and arise almost entirely from difficulties in accurately determining the mineral composition.

Comparison of Method 3 with Methods 1 and 2 shows that significantly different values of the mean conductivity can be obtained according to which approach is used; because the value of 1a has a much higher standard deviation than that of 3a the difference between the two values is not very significant.

Since many of the straight lines used in Methods 1 and 2 had a negative contact resistance, Method 3 is clearly superior. Some support for the accuracy of the values found by Method 3 is given by the good agreement of these values with those found for the computed conductivity, Method 4, over the corresponding ranges of depths.

The significance of rock structure in the selection of representative specimens—The results in Table 2 show that for many coarse-grained rocks the normal laboratory specimen is too small to represent a large mass of the rock: even the thickest disks of coarse-grained granite appear to have the minerals arranged in parallel. It is therefore necessary to understand which structural features of a rock affect the probability of its minerals showing a series arrangement in laboratory specimens and so to establish some working relationship between the grain size and the minimum thickness required to give the 'bulk' or *in situ* conductivity.

Most rocks contain monomineral chains or aggregates which can cause an apparent increase in thermal conductivity; similar effects are caused by the presence of phenocrysts.

If it is assumed that the monomineral chains are perpendicular to the faces of a disk, a laboratory specimen will give the bulk conductivity only when its thickness is greater than the length *l* of the longest chain. When the thickness of a disk is just less than *l* at least one of the chains of minerals will run directly across the specimen; if this chain is composed of a highly conducting mineral, heat will be transmitted across the disk more rapidly than it would if a few grains of a poorly conducting mineral were interposed. The increased conductivity of the disk renders it unrepresentative of the rock. As the thickness of the specimen is decreased, the conductivity will increase until the thickness is less than the size *m* of the smallest grain when the minerals are said to have a parallel arrangement. Thus the apparent conductivity of the rock will vary from a low conductivity equal to the bulk conductivity when the specimen thickness is greater than *l*, to a comparatively high conductivity when the specimen thickness is less than *m*. In practice, the chains of minerals have a great range of lengths and are usually at all angles to the faces of the specimen. Other wide variations in rock texture occur which make a theoretical approach difficult.

The present work suggests that before a disk may definitely be treated as having a series arrangement of minerals, the ratio of the disk thickness D to the average grain size G should be at least 15. This does not preclude the possibility of using specimens with much lower values of D/G provided it is quite certain that there are few monomineral aggregates and that the grain size is very even. In general, however, it seems probable that for specimens in which D/G is less than ten, a computation of thermal conductivity assuming a parallel arrangement of minerals will give results closer to the measured conductivity than a similar calculation assuming a series arrangement. For disks which have a value of D/G lying between 10 and 15 there will be some complicated combination of series and parallel elements which will cause the measured conductivity to lie between the series computed and parallel computed conductivities.

The coarse-grained granites from Hole 1 have been very thoroughly investigated and the conductivities computed from their mineral compositions gave the first clue to the inadequacy of the normal laboratory specimen. It was found that in all the disks, even the thickest ones (no. 15 and 64), the minerals were clearly arranged in parallel: Specimen 15 had a D/G value of 6 and Specimen 64 a D/G value of 8. It had been guessed that all the disks up to 6 mm thick had the minerals arranged in parallel since they were quite transluscent; some of the 8 mm disks were also transluscent but all other disks were opaque.

Many of the slides of the coarse-grained granites showed small xenolithic patches rich in biotite. The effect of the inclusion of a macroscopic xenolith of this composition in the disks from 35 ft has been noted in the section on computed conductivities.

For porphyritic rocks and those with a noticeably uneven grain size the measured conductivity of normal laboratory specimens lies between the series computed and parallel computed conductivity. A typical porphyritic specimen (10 from Hole 3) consists of phenocrysts of quartz, orthoclase, and plagioclase, $D/G = 3$, in a groundmass of the same minerals, $D/G = 28$, in approximately equal amounts. Similar wide differences of D/G values are shown by a microgranodiorite (Hole 1, 25 ft) which has an average grain size of 0.5 mm but contains several grains 3 mm long, and by a partly greisenised fine-grained granite (Hole 3, 394 ft) in which the grain size has been reduced in places by the alteration of orthoclase to a fine aggregate of mica flakes. In all these rocks, and many others, the conductivity decreases as the disk thickness increases thus providing further evidence of a mixed series and parallel arrangement of minerals, and for the inadequacy of the normal laboratory specimen.

The rock from 470 ft in Hole 2 is a good example of the difficulties encountered in correlating the computed and measured conductivities. The groundmass was too fine grained for accurate measurements on the individual disks whereas the two slides showed differences in composition due to the porphyritic texture of the rock.

In the even-grained diorites from Hole 2 it appears that the minerals are dominantly arranged in series. The alteration in the rocks makes it difficult to determine accurately the average grain size and hence to obtain reliable maximum and minimum values of D/G, but using the original grain size of the primary minerals these values are 12 and 4; allowing for the alteration, it is estimated that the values are 30 and 10.

It is doubtful if it will ever be possible to predict the exact thickness required in the general case of a rock containing more than one mineral. However, experience with these rocks has shown that a thin section should be examined before disks are cut.

The effect of moisture content on porous rocks—In the past, investigations into the variation of thermal conductivity with changes in water content of a porous rock have been hampered either by the use of steady-state apparatus with long time lags or by the use of transient methods; both methods lead to a non-static distribution of moisture in the specimens. The divided bars used in the present work have considerably reduced the time lag difficulties.

Three types of rock were investigated but only one will be discussed in detail in this paper. This rock was a porous sandy shale obtained from an outcrop instead of from a borehole as were the rest of the rocks. Cores were drilled parallel and perpendicular to the bedding and coated with a layer of waterproof plastic paint. Attempts to drill at various angles to the bedding resulted in complete failure because of splitting along the planes when either the cores or disks were being prepared. Ten disks were cut from the core drilled perpendicular to the bedding and five disks were cut from the core drilled parallel to the bedding; the thickness of the disks ranged from 1.5 to 8 mm.

For many geophysical problems only the dry or the saturated thermal conductivity of a rock is required but there are numerous fields, for example, building materials and mine ventilation, where a knowledge of heat losses through damp porous media is required. The thermal conductivity of each set of disks was therefore determined for the saturated state, and for a number of different unsaturated states with dry contacts between the bars and disks. The results for the porous shale are shown in Tables 4 and 5.

In view of the observations by other workers [*Benfield*, 1939; *Clark*, 1941; *Mossop* and *Gafner*, 1951] the results are rather surprising since they show large variations of conductivity with relatively small changes in water content. This point is emphasized by the lines shown in Figure 3 which were obtained using coarse-grained granites. However, for the reasons given in the section on the use of single disks, these results are not regarded as reliable as those for the very fine-grained porous shale.

TABLE 4 – *Variation of thermal conductivity with water content; heat flowing perpendicular to bedding of weathered shale; ten specimens*

Water content by volume pct	Thermal conductivity	Standard deviation
pct	cal/cm sec °C	pct

8.9	0.0074	0.9
5.7	0.0065	4.4
3.4	0.0062	4.4
1.6	0.0057	3.7
0.0	0.0047	3.3

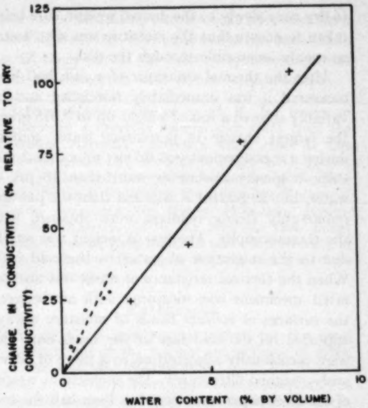

FIG. 3 – Percentage change in conductivity due to increase in water content; the crosses and the full line were obtained with a badly weathered coarse-grained granite; the points and the dashed line were obtained with a slightly weathered coarse-grained granite; in both cases the highest water content was obtained by applying a pressure of 150 lb/in² to all specimens

Each disk was dried to constant weight and the thermal resistance was measured on the guard ring apparatus with dry contacts between the faces of the disk and bars. The disks were then immersed in water at normal room pressure until they reached a constant weight after a few days. The thermal conductivity of each set of disks was found in the usual manner using liquid contacts; each disk was weighed before and after measurement and showed no significant change in weight. Experiments with an extra disk ten mm thick and immersed in water containing a dye indicated that the water penetration of the disks was uniform when saturated at room pressure. However, it was later found that when the rocks were immersed in water at 150 lb/in² they absorbed more water and reached a new saturated constant weight. That this increase in the amount of water taken up was not entirely due to any permanent alteration in the structure of the rock was indicated when the specimens were dried and again soaked to constant weight at normal pressures; the amount of water absorbed, although slightly higher than that first observed, was still less than the amounts taken up under pressure. Vacuum drying and letting the water in at this reduced pressure gave little improvement over the method of soaking in water at room pressures.

The intermediate unsaturated states were obtained by selecting a convenient percentage of water and calculating the weight of each disk necessary to obtain this percentage. After the disk was saturated at normal pressure it was allowed to dry very slowly to the desired weight, care being taken to ensure that the moisture was distributed as evenly as possible through the disk.

After the thermal resistance of a disk had been measured it was immediately reweighed and invariably showed a loss of weight up to 0.015 gram; the largest change in percentage water content during a measurement was 0.7 pct on a disk 2 mm thick originally containing more than 10 pct of water, but in general it was less than 0.2 pct and remarkably steady readings were obtained with the thermocouples. The loss of weight was partly due to the migration of water to the cold face. When the thermal resistance of moist but unsaturated specimens was measured with air between the surfaces of contact beads of moisture always appeared on the cold face of the brass bars and were occasionally absorbed on to a piece of previously weighed filter paper. The increase in weight of the filter paper was never less than half the loss in weight of the specimen; the discrepancies were mainly due to the small quantities of moisture involved although there was probably a slight loss of one or two milligrams when transferring the specimen from the balance to the apparatus and back again. However, because of the waterproof paint round the sides of each specimen, it is doubtful if any water was lost to the atmosphere while the specimen was between the bars. That the migration of water to the cold face was due to a thermal gradient and not due to gravity was shown by reversing the thermostatic baths and heating the lower end and cooling the upper end of the apparatus; when a moist specimen was placed between the bars, beads of moisture appeared on the contact face of the upper cold bar but not on the face of the lower hot bar. When the condensation was first noticed experiments were made with greased surfaces to prevent the water getting out of the disk. Unfortunately, the grease was found to soak into the surfaces and it could not be removed even when the specimen was boiled in carbon tetrachloride and then benzene.

Complications arose from the fact that in the shales some of the water was undoubtedly adsorbed; this was indicated by micrometer measurements of the disks which showed that they swelled by a few ten thousandths of an inch when saturated. This did not occur in the granites. Experiments with liquids other than water, say an organic liquid or even a low-melting-point solder, would probably give results which could be interpreted more easily, since the problems of adsorbed films of liquid and the transfer of heat by the vapor phase would be considerably reduced. It is surprising that no one appears to have done this when checking a theory of conduction of heat in porous media.

In any of the moist states there is, of course, a possibility of water penetrating the disks in a non-uniform manner even though precautions were taken to prevent this. Fortunately, the standard deviations (Tables 4 and 5) indicate that when a set of disks containing a given percentage of water was measured the average thermal resistance per unit thickness was reasonably constant from disk to disk; these consistent results suggest that either the water penetration was fairly uniform or if it was non-uniform this does not upset the results very much.

There is also a possibility that the migration of water to the cold face may give rise to a variable contact resistance. This probably does occur immediately after the disk is introduced but after five to ten minutes a very steady state is reached, the variation between successive readings of any given thermocouple being no greater than that for impervious rocks. The probable mechanism here is that immediately after the damp disk is placed between the bars, water begins to migrate to the cold face and there condenses. When sufficient moisture has condensed to block up the pores of the cold face of the disk the migration ceases since all exits are blocked either by the condensation at the cold face or by the plastic paint on the outside surface. The condition inside the disk is therefore one of slightly uneven but stable moisture distribution. After the steady state has been reached there is, in effect, one wet contact and one dry contact. Some support for this is given by the values for the resistance of the various films of contact. For the dry disks the contact resistance of each air film was 2.4 cm brass whereas the resistance for each liquid film for the saturated disks was 0.2 cm brass; for the moist specimens the combined resistance of the two contact films was 3.1 cm brass.

The most important state of the rock with regard to crustal heat flow is the saturated state. In saturated or nearly saturated media it is practically impossible to make moisture move down a temperature gradient [*Hutcheon* and *Paxton*, 1952; *Kuzmak* and *Sereda*, 1957] so that the moisture migration problem will not arise in heat flow measurements. However, there is considerable doubt as to when a rock is saturated. The present work has shown that at higher pressures more water can be squeezed into a rock but that it is unlikely that this is due to a permanent alteration in the structure of the rock. The conclusion then, is that at room pressures the rock is not saturated merely by being soaked in a dish of water or by water being let in under vacuum. If the conductivity of a porous rock from depth is required some reliable technique for saturating the rock must be developed.

Discussion—Even if allowances are made for all the difficulties described in the previous sections and for the changes of pressure and temperature when a rock is brought to the surface, there is still a doubt as to whether a specimen is truly representative of the rock *in situ*. Rocks have beed known to shatter completely when they are being cut, implying the presence of internal strains and cracks produced by the removal of pressure ann subsequent working. Since this is a permanent physical change, the reapplication of pressure probably does not completely restore the rock to its original state. An interesting, though somewhat extreme, case of what can happen is given by *Godridge* [1956]; he shows that very light mechanical maltreatment of coal samples results in a 10 to 15 pct reduction in thermal conductivity.

The only way these doubts can be removed is by a systematic investigation over a wide variety of rock types, comparing the laboratory results with an independent method of measuring thermal conductivities *in situ*. If it is known that there are no inconsistencies in the walls of a borehole then a probe technique [*Blackwell*, 1954; *Crowe*, 1956] can be used. However if there are irregularities caused by drilling, then, to increase the depth of penetration of heat and so reduce the effects of irregular walls, it will be necessary to use a technique similar to that tried in Tasmania [*Beck* and others, 1956] where a long length of borehole was heated for a long time.

Conclusions—It has been shown that for a given apparatus and known tolerances of rock machining, rapid and reliable measurements of thermal conductivity can be made on single disks. The results from this method demonstrate that for many coarse-grained rocks the normal laboratory specimens are so small that they give a value of the conductivity significantly higher than the thermal conductivity of a large mass of the rock. This is due to the minerals showing a dominantly parallel instead of a series arrangement. Therefore before disks are cut a thin section of a rock should be examined to determine the average grain size; disks thick enough to be representative of a large mass of the rock can then be prepared. The methods of saturating porous rocks have also been found inadequate. When allowance has been made for all these effects the laboratory measurements must be correlated with *in-situ* measurements.

Acknowledgments—One of us (A. E. B.) wishes to acknowledge a generous maintenance grant from the Australian National University where most of this work was carried out. We wish to thank J. C. Jaeger, G. A. Joplin, and many other colleagues at the Australian National University, the Australian Bureau of Mineral Resources, the Snowy Mountains Hydro-Electric Authority, the U. K. National Coal Board Mining Research Establishment, and the University of Western Ontario for many helpful, and sometimes heated, discussions.

Radioactive Ages of Micas from Granitic Rocks by Rb-Sr and K-A Methods

L. T. ALDRICH, G. W. WETHERILL, G. L. DAVIS, AND G. R. TILTON

Abstract—Analytical data and ages are given for K-A, Rb-Sr, U-Pb and Th-Pb ages from a number of locations. Comparisons of the ages obtained indicate (a) that K-A and Rb-Sr ages of mica usually agree when modern laboratory determined values of the decay constants of K^{40} and Rb^{87} are used; (b) that the K-A and Rb-Sr ages of micas agree with the U-Pb ages of cogenetic uraninite, zircon, and monazite when the U-Pb ages are concordant; (c) that when the U-Pb ages of these uranium minerals are discordant, the mica ages agree best with the Pb^{207}-Pb^{206} age; (d) that the pattern of K-A and Rb-Sr ages of micas can be most simply explained by postulating the loss of variable but small amounts of argon from the mineral.

The usefulness of a reliable method by which either relative or absolute ages of rocks could be measured has long been appreciated. That concordant, and therefore probably reliable, U-Pb ages of pegmatitic uraninites are usually obtained was demonstrated by *Wasserburg* and *Hayden* [1955]. The frequent occurrence of discordant ages of other uranium- and thorium-containing minerals is also well known. This paper presents the results of the continuation of the studies of cogenetic minerals at the Carnegie Institution. In this work the measurements of the K-A and Rb-Sr ages are emphasized. In some cases U-Pb and Th-Pb ages have also been obtained. The comparisons of all radioactive ages have proved to be informative and helpful in the interpretation required to obtain the age of the rock studied. A study of zircons from granites and pegmatites [*Tilton* and others, 1957] is another example of this kind of work.

For nearly a decade it has been possible to measure the argon content of potassium minerals. The results have been summarized by *Wetherill* and others [1956b] who point out that the decay constant λ_e obtained from the measurements of the ratio A^{40}/K^{40} for micas and the concordant U-Pb ages of cogenetic uraninites is in good agreement with that found from laboratory measurements of the decay constants of K^{40} [*Wetherill*, 1957].

The presence of radiogenic Sr^{87} in rubidium minerals has been known for two decades. The measurements of the decay constant of Rb^{87} have been discussed by *Aldrich* and others [1956b]. The empirical determination of the Rb^{87} decay constant from measurements on cogenetic minerals containing uranium and rubidium gives a value for λ_β of $1.39 \pm 0.05 \times 10^{-11}\text{yr}^{-1}$. Because of the difficulties of analysis before 1948, measurements of the ratio Sr^{87}/Rb^{87} were few, and confined to lepidolites where the strontium content of the mica could reasonably be assumed to be entirely radiogenic. Most of these measurements were made by *Ahrens* [1955] and his co-workers by spectrochemical methods. Ahrens pointed out the difficulties of his techniques as had others [*Nicolaysen*, 1954]. As a result, his measurements must be assumed to be semiquantitative in nature. The possibility of determining Rb-Sr ages of biotites was pointed out by *Whiting* [1951] from his spectrochemical determinations of the ratio of strontium to rubidium. The high percentage of radiogenic Sr^{87} in the Sr^{87} of these minerals was confirmed by *Herzog* and others [1953], and *Aldrich* and others [1955].

Laboratory measurements of the decay constant of Rb^{87} have ranged from 1.09 to $1.73 \times 10^{-11}\text{yr}^{-1}$ with the larger number of determinations near 1.15. The difficulty of properly forming and counting the thin sources necessary for the weak (average energy of 45 kilovolts) beta-particles emitted in the decay of Rb^{87} could account for this low value. The recent careful work of Huster and Rausch (private communication) seems to favor an intermediate value for this constant of $\lambda_\beta = 1.39 \times 10^{-11}\text{yr}^{-1}$, which is in excellent agreement with the geologically-determined value found at the Carnegie Institution. This agreement does not remove the need for further laboratory corroboration of the value of the decay constant. The decay constants of K^{40}, Rb^{87}, Th^{232}, U^{235} and U^{238} for the work discussed in this paper are given in Table 1.

Analytical procedures—The analytical procedures are based on the method of isotope dilution and have been described in detail elsewhere

TABLE 1 – *Decay constants and isotopic abundances of radioactive isotopes used in this paper*

Isotope	Decay constants	Isotopic abundance
K^{40}	4.72×10^{-10} yr^{-1} (beta decay) 0.585×10^{-10} yr^{-1} (K-capture)	1.22×10^{-4} g/g K
Rb^{87}	1.39×10^{-11} yr^{-1}	0.283 g/g Rb
Th^{232}	4.99×10^{-11} yr^{-1}	1 g/g Th
U^{235}	9.72×10^{-10} yr^{-1}	0.00711 g/g U
U^{238}	1.54×10^{-10} yr^{-1}	0.9929 g/g U

[*Wetherill* and others, 1956a; *Aldrich* and others, 1956a; *Aldrich*, 1956]. The one simplification which has been made, now that both K and Rb determinations for the same sample are desired, is to add a mixture of K^{41} and Rb^{87} tracer to the same aliquot of the sample. A single mass spectrometer run in which both ratios, K^{39}/K^{41} and Rb^{87}/Rb^{85}, of the solution of the aliquot and the mixed tracer are measured suffices to make these determinations.

The analytical procedure used for the determination of U, Th, and Pb in uraninite has not been presented previously. A uraninite crystal is hand-crushed to −20 mesh, and fresh unaltered portions hand-picked with the aid of a low-power microscope. A 20–50 mg sample is dissolved in a small amount of redistilled nitric acid and then diluted to 100 ml in a volumetric flask. To 200 microliters of this solution is added 1 ml of U^{235} tracer containing 5.93 μg U^{235} and less than 0.005 μg U^{238}, and 0.250 ml of Th^{230} tracer containing 7.14 μg Th^{230} and 0.762 μg Th^{232}. This solution is diluted and heated to equilibrate the U and Th of sample and tracer solutions, and dried. A portion of this mixture is taken up in two drops of 0.1 M HNO_3 and placed on an outgassed tantalum ribbon in the mass spectrometer source. The U analysis is completed by measurement of UO_2^+ ions emitted thermionically from the ribbon. The Th is emitted at considerably higher temperatures as the ThO^+ ion and is readily located by the UO^+ peaks. From the U^{238}/U^{235} and Th^{232}/Th^{230} ratios the U and Th concentrations of the dissolved sample are calculated.

Two analyses are required to determine the isotopic composition and concentration of the Pb in a uraninite. To 2 ml of the uraninite solution is added 20 μg of Pb^{208} tracer solution. The mixture is equilibrated and extracted as the dithizonate complex into chloroform at pH 8.5 in the presence of potassium cyanide and ammonium citrate. Pb is stripped into two per cent HNO_3, and PbS is precipitated from solution at pH 4.5. The PbS is then placed on an outgassed tantalum ribbon and dried with some of the ammonium nitrate solution from which it is precipitated. The lead is analyzed as Pb^+ emitted thermionically from the ribbon in the mass spectrometer source. The procedure above is repeated omitting the Pb^{208} tracer and the isotopic composition of the Pb in the uraninite obtained. From these two analyses the data required to determine the radiogenic Pb^{206}, Pb^{207}, and Pb^{208} content of the uraninite are obtained. The analyses have an error of two per cent in the Pb concentration and one per cent in the isotopic composition of the uraninite leads.

Analytical data—The analytical data are presented in four tables. Unless otherwise indicated the errors of the analytical measurements of concentrations of K, Rb, Sr^{87}, and A^{40} are less than three per cent. Table 2 gives the analytical data for five pegmatites for which K-A, Rb-Sr data of micas and U-Pb data for uraninites have been obtained. Table 3 contains similar data for additional pegmatites which have other uraninum- and thorium-containing minerals. Table 4 presents analytical data for granites from which both micas and zircons have been analyzed. The U, Th, and Pb analytical data are elsewhere [*Tilton* and others, 1957]. Table 5 gives the analytical data for micas from granites and pegmatites from which no U-Pb measurements have been obtained.

Ages—Using the decay constants of Table 1, ages may be calculated for each of the minerals of Tables 2–5. For K-A ages the results are calculated from

$$T = \frac{10^{10}}{5.30} \log_e \left(1 + 9.06 \frac{A^{40}}{K^{40}}\right) \text{ yr}$$

Each of the other four parent-daughter ages is given by

$$T = \frac{1}{\lambda} \log_e \left(1 + \frac{N_d}{N_p}\right)$$

where λ is the decay constant governing the system and N_d/N_p is the ratio of the number of daughter atoms to the number of parent atoms found in the mineral. The Pb^{207}-Pb^{206} age is obtained from curves plotted from the equation

$$\frac{N(Pb^{207})}{N(Pb^{206})} = \frac{1}{137.8} \frac{(e^{\lambda 235 T} - 1)}{(e^{\lambda 238 T} - 1)}$$

The data of Tables 2–5 are given in terms of ages in Tables 6–9. The uncertainty in the ages

because of analytical errors is less than five per cent unless indicated. Table 6 indicates the agreement of K-A and Rb-Sr ages with concordant U-Pb ages from pegmatites for which the latter ages are available. The ages for which this agreement has been measured are distributed over a time interval of 350 to 2700 m y.

Table 7 shows that for two pegmatites whose history is such that uranium- and thorium-containing minerals give ages which do not agree micas still give concordant K-A and Rb-Sr ages.

Table 8 demonstrates, first, that micas from granites generally give K-A and Rb-Sr ages which agree. Secondly, if the U-Pb ages of the zircon

are concordant, all four ages agree. Finally, if the U-Pb ages of the zircons disagree, the values for Pb^{207}-Pb^{206} ages are closest to the K-A and Rb-Sr ages of the associated micas.

Table 9 gives the K-A and Rb-Sr ages of micas from several pegmatites and granites for which no U-Pb ages have been accurately determined. The general agreement of these two ages is very satisfactory. The range in age for which this agreement exists is from 100 to 2600 m y.

Discussion—The K-A and Rb-Sr ages of Tables 6–9 together with the data of *Jeffery* [1956] are plotted in Figure 1. They are given in the form of a histogram of the ratio of the Rb-Sr age to the K-A

age of micas. The histogram includes all micas analyzed at the Carnegie Institution before February 1957. Where more than one mica from a rock has been analyzed the ratios are averaged and plotted as one square in the histogram unless the two ratios are markedly different. The histogram shows two particular characteristics of the ages. First, the K-A and Rb-Sr ages agree within ten per cent for over 60 pct of the rocks measured. Second, when the two ages disagree by more than ten per cent, the Rb-Sr age is nearly always greater than the K-A age. This is interpreted as an indication of argon leakage from the mica. Since argon may have leaked, the possibility remains that some of the Sr^{87} may also have been lost from the mica so that neither age can safely be considered to be absolute.

The first characteristic shown by the histogram

[a] Zircon has extensive radiation damage, contains 2060 ppm U, 8120 ppm Th.

[b] Zircon has little radiation damage, contains 414 ppm U, 1337 ppm Th.

demonstrates the general occurrence of the agreement of the K-A and Rb-Sr ages of micas from granitic rocks. Tables 7 and 8 demonstrate that the agreement of K-A and Rb-Sr ages is common even when the U-Pb ages of minerals from the same rock are discordant. This work indicates that the probability of obtaining concordant ages by K-A and Rb-Sr methods on mica is exceeded only by that of obtaining concordant U-Pb ages on pegmatitic uraninites. This is an empirical fact which has no obvious physical or chemical basis. It should be pointed out, that the decay of U and Th involves a far greater disturbance of the crystal structure than does the decay of either Rb or K. Sr^{87} and A^{40} originate with a maximum recoil energy of two and 24 electron volts, respectively, while the decay series of U^{238}, U^{235} and Th to lead involve the emission of six to eight alpha particles which produce nuclei with recoil energies on the order of 100,000 electron volts each. The fact that metamict zircon, the Wichita Mountain sample, for example, has given concordant isotopic ages indicates that radiation damage is not the sole cause of discordant ages, but it may play a role in promoting lead loss when it does occur. When the K-A and Rb-Sr ages of a mica disagree, both ages must be regarded with suspicion.

The preceding data indicate that micas give reliable ages for a majority of granitic rock samples. It is then reasonable to discuss a few conclusions of geological interest.

The measurements, including those of *Jeffery* [1956] and *Nicolaysen* [1954], demonstrate that rocks approximately 2600 m y old exist in North America, Africa, and Australia. Since these pegmatites intrude volcanic and sedimentary formations, rocks older than these pegmatites are known to exist. Mica probably offers the most attractive possibility for determining the ages of these more ancient rocks. The Varuträsk pegmatite should not be grouped with these oldest pegmatites as suggested by *Ahrens* [1955].

Another group of measurements of interest is that of the intrusive rocks of the Granville subprovince. From field relationships, *Satterly* and *Hewitt* [1955] have determined that in the sequence of intrusive rocks in the Bancroft region the Fission Mine belongs to the youngest group and the

nepheline pegmatite belongs to the oldest. From the data presented above one can say either that the time interval between these extremes is too small to be measured or that the activity during which the younger pegmatites were emplaced altered the biotites from the nepheline rocks in such a way that all traces of their previous history were removed.

A third group of samples is of some interest because of their geographic and chronological proximity. These are the twelve granites and pegmatites in Arizona, New Mexico, Colorado, and Wyoming the value of whose ages is close to 1350 m y. The close agreement of these ages is believed to be an indication of some large scale process of granitic rock formation which occurred 1300 to 1400 m y ago, one which has not been eradicated by any subsequent geological event such as the Laramide orogeny. Before these measurements there was no basis for associating these rocks.

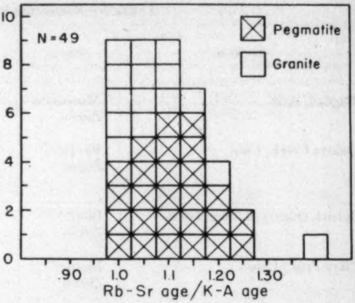

FIG. 1 – **Histogram of the ratio of the Rb-Sr age to the K-A age of micas from granites and pegmatites**

The two Pikes Peak samples had been thought from field evidence to be quite different in age [*Lovering* and *Goddard*, 1950]. From the K-A and Rb-Sr measurements it appears that, if a difference exists, it is less than the error of measurement. The Pikes Peak sample from the road cut between Manitou Springs and Pikes Peak Road also places an upper limit on the age of the Cambrian formation which unconformably overlies the granite. From these measurements it can be stated with considerable certainty that the Cambrian formation is younger than 1100 m y. While this may be considered an obvious fact, the statement is made to point out the difficulty of placing accurate ages on positions in the stratigraphic column. Intrusive rocks which cut one member of the column and are overlain unconformably by a closely adjacent younger member are rare. Thus any measurement, such as this one, which places an upper limit on the absolute age of a sedimentary rock of known geologic age is of considerable value until methods of measuring ages of minerals of sedimentary rocks are well established.

Several things may be said about the South African samples. First the diversity of the Cape granite ages may reflect the geologic history of the rock [*Nicolaysen*, 1954] in that the granite was depressed to great depth during the Devonian. The 'Cape System' rests unconformably on the Cape granite. The agreement of the Jakkalswater ages indicates that they are contemporaneous with the Steenkampskrall monazite analyzed by *Tilton* and *Nicolaysen* [1957]. The micas from the Belgian Congo and Tanganyika were thought to have a sequence which is not evident in the measured ages. The Tanganyika pegmatite was believed to be considerably older. Since these ages all agree within the errors of measurement, either the emplacement of all the pegmatites was simultaneous or else the event during which the Belgian Congo micas were formed removed all the evidence of the earlier history of the Tanganyika mica. The Bikita and Kubuta micas are from the group collected by Nicolaysen. The Bikita sample gives an age in good agreement with that found in Holmes for monazites from neighboring pegmatites. The Kubuta sample has the highest ratio, Sr^{87}/Rb^{87}, of any of those measured at this laboratory to this date. It also has the highest ratio A^{40}/K^{40}.

Conclusions—The results reported in the present study indicate that the rubidium-strontium and potassium-argon ages determined on single specimens of mica often agree within five to ten per cent. Since the two ages do not always agree, it should be emphasized that it is necessary to measure both ages on a mica in order to have full confidence in the result. When the two mica ages do agree, it is highly probable that they give the absolute age of the mica. Concordant uranium-lead ages given by zircon from granites and uraninite or monazite from pegmatites have been found to agree with K-A and Rb-Sr ages of mica. In such cases it is probable that the age closely represents the time of crystallization of the rock as a whole. Finally, the agreement of the two mica ages can often be preserved through processes which seriously alter the isotopic lead ages. Examples are the Brown Derby and Harding pegmatites and the Quartz Creek, Bagdad, Pikes Peak, and Capetown granites.

Acknowledgments—For assistance in sample collection we are indebted to J. A. Norton, D. Brobst, C. A. Anderson, and Warren B. Hamilton of the U. S. Geological Survey; S. C. Robinson of the Canadian Geological Survey; D. F. Hewitt and S. Ferguson of the Ontario Department of Mines; and our colleagues at the Geophysical Laboratory, particularly L. O. Nicolaysen and William MacKenzie. L. Cahen of the Museum of the Belgian Congo, Tervuren, Belgium, provided the samples from the Belgian Congo. The cooperation of all these interested persons is gratefully acknowledged.

APPENDIX

The following descriptions of the minerals for which ages are given in this paper are based on examinations of thin sections of the rocks, binocular microscopic determination of homogeneity, x-ray examination and identification, whichever is applicable. In cases where descriptions have previously been given, only new observations are listed. The samples are arranged in order of increasing age in each of three groups.

PEGMATITES CONTAINING URANINITES WITH ACCOMPANYING MICAS

Chestnut Flat Mine, Mitchell County, North Carolina—This mine is located about six miles north-northwest of Spruce Pine [*Olson*, 1944]. The uraninite specimen was collected from the margin of the core of the pegmatite as an aggregate of centimeter-sized pieces in a muscovite matrix. The mica was embrittled in the neighborhood of the uraninite, which was covered by a thin layer of orange-yellow alteration products. A clean sample was obtained by hand-picking the broken crystals. Fresh muscovite and microcline were obtained nearby where no uraninite occurred.

Fission Mine, Cardiff Township, Haliburton County, Ontario—Cubes of uraninite in a fluorite matrix were collected from Pit 4, 1.75 miles northwest of Wilberforce. *Satterly* and *Hewitt* [1955] list detailed information about the deposit. The uraninite required very little hand-picking for purification. A sample of clean biotite was collected from the same vein.

Cardiff Uranium Mine, Cardiff Township, Haliburton County, Ontario—This mine is located three miles south of the village of Wilberforce. The uraninite occurs as cubes in a matrix of fluorite, calcite, and apatite. The sample was collected from the north adit. Unchloritized biotite was collected from the same vein. A description of the property is given in some detail by Satterly and Hewitt.

Bob Ingersoll Mine, Keystone, South Dakota—This pegmatite is described by *Page* and others [1953]. The uraninite was collected from dumped material from Dike 1 as a single piece of pure mineral weighing about 250 g. A personal communication from Page states that the occurrence is not the one reported by him. This uraninite came from the outer margin of Dike 1, just outside the lepidolite body. Lepidolite and purple and white muscovite were also collected from the pegmatite.

Viking Lake pegmatite, Goldfields region, Saskatchewan—Specimens of uraninite (coarse powder), biotite, and other minerals were received from S. C. Robinson of the Geological Survey of Canada. These were collected one-half mile north of the north arm of Viking Lake from "an exceptional zoned pegmatite . . . in the Beaverlodge camp, has an outer envelope of quartz and euhedral microcline, an intermediate zone of highly sericitized sodium feldspar with some biotite and accessory magnetite and pyrochlore, and a core of brecciated but fresh microcline-albite-quartz-biotite rock which contains abundant pyrochlore, titanite and magnetite, and accessory uraninite, urano-thorite, cyrtolite, meta-allanite, and allanite." (S. C. Robinson, 1955, *Mineralogy and geochemistry of uranium in Canada*, preprint 284, Nuclear Engineering and Science Congress, publ. Amer. Inst. Chem. Eng.). X-ray examination of the biotite produced an unsatisfactory diffraction pattern indicating extensive chloritization.

Bikita Quarry, Bikita district, Southern Rhodesia—The isotopic analysis of a sample of monazite from the Ebonite Tantalum Claims has been reported by *Holmes* [1954]. The ages have been recalculated from the uranium and lead data given. Lepidolite from Bikita collected by L. O. Nicolaysen is sample N-45 of the intralaboratory series [*Aldrich* and others, 1956c].

GRANITES

Conway Granite, Redstone Quarry, Redstone, New Hampshire—The usual pink Conway granite and a green hastingsite phase were collected at the quarry at Redstone. The area and its rocks are described by *Billings* [1928, 1956]. The biotite from the pink granite occurred as ragged grains, partially chloritized, but a good sample was obtained by magnetic separation. The green rock provided good biotite. This phase also contains hornblende, apatite, magnetite and several rare minerals.

Cape Granite, Lower Cable Station Quarry, Capetown, South Africa—The biotite from this rock is partially chloritized [*Nicolaysen*, 1954].

Wichita Mountains, Oklahoma—The zircon is from a pegmatite on Quanah Mountain. *Tilton* and others [1957] give a description of the samples. The biotite was separated from a granite collected from a road cut on the west shore of Lake Altus Reservoir, 0.65 miles south of the Quartz Mountain State Park. This location was suggested by W. C. Hamilton of the U. S. Geological Survey and the sample was collected by E. E. Glick, B. R. Haley, and P. T. Stafford of the Survey.

Pikes Peak granite, near Manitou Springs, Colorado—Although collected from a road cut between Manitou Springs and Pikes Peak Road, this granite shows evidence of considerable alteration. Thin-section examination shows that the feldspar has been kaolinized and the mica extensively chloritized. This general characteristic is noted by *Lovering* and *Goddard* [1950].

Granite from the top of Pikes Peak, Colorado—A red, fine-grained rock collected from near the parking lot at the end of the toll-road at the top of the mountain yielded a sample of biotite which is partially chloritized.

Petrick Quarry, Llano, Texas—This granite is dark pink, somewhat porphyritic and coarse grained. The biotite is not chloritized. A description is given by *Barnes* and others [1947]. The location is north of the intersection of Texas Routes 29 and 261, 17 mi east of Llano.

Quartz Creek granite, Quartz Creek district, near Gunnison, Colorado—Described by *Aldrich* and others [1956a] after *Staatz* and *Trites* [1955]. The biotite is not chloritized but shows some signs of having been leached. It contains pleochroic halos and rod-like inclusions. Some secondary muscovite was noted.

Uncompahgre granite, Unaweep Canyon, Mesa County, Colorado—This is a slightly altered, white muscovite granite with accessory biotite and zircon.

Sandia granite, near Albuquerque, New Mexico—This white granite is exposed on the lower part of the Sandia Escarpment north east of Albuquerque. It is composed of sericitized plagioclase, biotite, apatite, rather large grains of sphene, and a little chlorite and magnetite.

Zoroaster granite (gneiss?) at the mouth just west of Zoroaster Creek Grand Canyon, Arizona—This rock occurs as "a rather massive, medium-grained, muscovite-biotite-granite" (*Carnegie Institution Yearbook 35*, 1935–1936, p. 330). It is overlain unconformably by sandstones and basal breccia of the Tonto Platform. In thin section the rock has a crushed appearance, the biotite being curved and rusty. The muscovite is in good condition. Zoisite is present in minor amounts.

Lawler Peak granite, ¾ mile northeast of Lawler Peak, Bagdad, Arizona—The area is described by *Anderson* and others [1955]. Thin-section examination showed the presence of secondary muscovite formed from alteration of the plagioclase. The coarser primary muscovite was readily separated for analysis.

Granite, Sherman Mt. Quadrangle, Wyoming—Collected from road cut on U. S. Route 30, 18 mi east of Laramie. Petrographic examination of a thin-section showed that the biotite, containing inclusions of sphene or zircon, and pleochroic halos, was considerably chloritized, however, a good sample of biotite was separated for analysis.

Silver Plume granite, Silver Plume, Colorado—This granite was collected from a quarry half a mile west of Silver Plume. *Lovering* and *Godard* [1950] consider this granite to be representative of the Precambrian granites younger than the Pikes Peak granite. The material collected was a fine grained, gray, massive rock which contained biotite, moderately chloritized, muscovite, fluorite, and sphene.

Wind River granite, Wind River Canyon near Shoshone, Wyoming—This rock has been described by *Gwynne* [1938]. It was collected as the closest granite to the Bonneville pegmatites [*McLaughlin*, 1940]. Thin-section examination showed extensive chloritization of the biotite, which occurs in veins mixed with muscovite. The presence of hydrothermal muscovite was noted.

OTHER PEGMATITES

Pala, California—Lepidolite, interlaboratory series no. A 107.

Goulding-Keene Quarry, Bancroft, Ontario—Pegmatite 6.8 mi east of Bancroft, on the road to Herman on the west side of the York River. Nepheline-albite pegmatite with calcite, biotite, apatite and zircon. X-ray of biotite showed no chlorite.

Jakkalswater, Cape Province, South Africa—Muscovite; for description see *Nicolaysen* [1954].

Muika, Belgian Congo—Lepidolite; for description see *Nicolaysen* [1954].

Manano, Belgian Congo—Lepidolite, from Belgian Congo Museum. Pegmatites described by J. Thoreau in *Commémoration du 50e Anniversaire du Comité Spécial du Katanga*, Comtes Rendus du Congrès Scientifique, Elizabethville, 1950, vol. 2, pp. 333–368. Sample provided by L. Cahen.

Karema, Tanganyika Territory—Muscovite, from Ubendian belt. Sample provided by L. Cahen.

Harding Mine, Dixon, New Mexico—Lepidolite, purple and white muscovite and yellow and brown microlite were obtained from the pegmatite under the guidance of the owner, Arthur *Montgomery* [1953] who has described the geology of the area. The identification of the micas and the light colored microlite was verified by x-ray. The dark brown microlite (hatchettolite?) showed no structure, indicating complete destruction of the lattice by radioactivity. The purple micas have been discussed by *Schaller* and *Henderson* [1926].

Wickenberg, Arizona—Purple muscovite. The sample was collected from a pegmatite on the fork of San Domingo Wash near Riley's Place.

Brown Derby Mine, Ohio City, Gunnison County, Colorado—Lepidolite and muscovite. See *Aldrich* and others [1956a].

Pidlite Mine, Mora County, New Mexico—Lepidolite was collected with Arthur Montgomery from this pegmatite which has been described by *Jahns* [1953].

Bagdad, Arizona—Lepidolite was collected from a pegmatite in the Lawler Peak granite under the guidance of C. A. Anderson within ¼ mile of the granite location.

Bob Ingersoll Mine, Keystone, South Dakota—Purple muscovite, interlaboratory series no. A 106.

Varuträsk, Sweden—Lepidolite, interlaboratory series no. A 110.

Bridger Mountains, near Bonneville, Wyoming—Purple muscovite was collected at Locality 7 or 11 described by *McLaughlin* [1940].

Silverleaf Mine, S. E. Manitoba—Purple muscovite, interlaboratory series no. A 109.

Hearst, Ontario—Lepidolite obtained from S. A. Ferguson, Ontario Department of Mines, Timmins, Ontario. Collected from a pegmatite in pink granite occurring on Concession 4, Lot 7, Lowther Township.

Kubuta, Swaziland—Lepidolite collected and described by *Nicolaysen* [1954].

Areas of Tectonic Activity in the United States As Indicated by Earthquake Epicenters

G. P. WOOLLARD

Abstract—A study based on earthquake occurrences in the United States shows several zones of continuing seismic activity. Over the past 30 years there is a suggestion of systematic variations in seismic activity following what appears to be a three-year cycle which is superimposed on a longer period. Areas of activity can not be related to either geologic age or type of structure. In California transcurrent movement on known faults is associated with seismic activity. In the other western states activity is associated with the boundaries of areas of epeirogenic uplift and subsidence and appears to involve predominantly vertical crustal displacement. In the Midcontinent area activity for the most part is associated with positive crystalline rock tectonic elements and their borders. In the Appalachian area activity is associated with the zones of overthrusts and shear. A conspicuous zone of earthquakes paralleling the Appalachians from Missouri to the St. Lawrence River valley while not related to known geologic controls does follow a zone of better-than-normal seismic transmissibility. The depth of focus varies from area to area and appears to be related directly to crustal thickness and possibly also changes in crustal rigidity with depth. No direct relation is noted between areas of isostatic unbalance and seismic activity or variations in degree of seismic activity with changes in crustal thickness. For the most part, it appears local stress conditions are dominant in causing earthquakes.

Introduction—That the geographic distribution of earthquakes has tectonic and geologic significance has been recognized for many years. *Gutenberg* and *Richter* [1940] have pointed out that the principal seismic regions of the earth are distributed along the borders of great lines of folding marked by high chains of mountains and the great oceanic trenches. In general it has been observed that the intensity of seismic activity appears to be related to the geologic age of the tectonic elements involved; the older they are the less intense the seismic activity. However, the role of rejuvenation in causing earthquakes is indicated by the many earthquakes which occur in elevated former peneplains now forming plateaus. Regional stresses are also indicated in the old stable shield areas of low elevation by the occurrence of major earthquakes in areas such as the Mississippi River valley. Compressive and tensional forces, horizontal shear, and rotational forces all are observed to have been active in forming geologic tectonic units, and earthquakes are evidence of these forces in action. In some areas tectonic movement in association with individual earthquakes can be seen, in other areas there is no observable crustal displacement.

Over 90 pct of all earthquakes occur within the surficial crustal layer whose base is defined by the Mohorovicic discontinuity. The spatial distribution of focal points of origin of earthquakes and the frequency of earthquakes at different levels has significance as to tensional and compressional forces in the crust and outer mantle rocks. *Benioff* [1955] has shown that deep-focus earthquakes are systematic in location and define shear planes suggesting local underthrusting of the continents by the adjacent oceanic block. Deep-focus earthquakes are rare in the United States although they do occur in Mexico.

Various investigators have described geological associations noted with individual earthquakes and the tectonic movement involved. *Wood* [1947], *Gutenberg* [1943], and *Hill* and *Dibblee* [1953] have described the relation of earthquakes to transcurrent fault movement in Southern California. *Jones* [1938] has described the increase in depth of focus of earthquakes as the vent of Mauna Loa Volcano is approached on the island of Hawaii. *Barksdale* and *Combs* [1946] have described the association of earthquakes with the Puget Sound depression. *Taber* [1916], *Crickmay* and *Mitchell* [1935], and *MacCarthy* [1958] have commented upon the occurrence of earthquakes in association with the thrust fault area of the older Appalachians and the shear zones of the Atlantic Piedmont. *Collins* [1937] and *Billings* [1942] have noted a correlation of earthquakes with areas of granite intrusion in New England. *Leet* [1942] has attributed earthquakes and their alignment in the northeastern states to domal uplift of the Canadian shield as a result of crustal unloading occasioned by the melting of the Pleistocene ice cap. *Pardee* [1927] has described the association of earthquakes with the Bighorn Mountain uplift in Wyoming.

Jones [1915] and *Gianella* and *Callaghan* [1934] as well as others have described structural movement and fracture patterns developed as a consequence of earthquake activity in the Basin and Range area of Utah and Nevada.

Callaghan and *Gianella* [1935], *Larson* [1957], *Leet* [1936], *Pardee* [1950], *Rockwood* [1872–1886], *Slemmons* [1957], and *Whittier* [1957] have collected valuable information regarding various earthquakes and associated tectonic features. The results of the above works have been incorporated into the regional analyses of tectonic activity.

The present study differs from these earlier ones in that the writer has undertaken to examine the United States as a whole with attention to: (1) areas experiencing tectonic movement as evinced by earthquakes, (2) possible changes in earthquake activity and location with time, (3) the geologic associations in areas now undergoing structural dislocation as indicated by earthquakes, and (4) variations in depth of origin of earthquakes, especially as related to geologic provinces, crustal structure and isostatic compensation. This study was started in 1937 under the auspices of the Special Committee for the Geophysical and Geological Study of the Continents of the Union and with the cooperation of the late N. H. Heck of the U. S. Coast and Geodetic Survey and late H. F. Reid of Johns Hopkins University. While there have been no previous published reports on the study, a map showing the location of all known earthquakes in the United States was exhibited at the 1939 meeting of the International Union of Geodesy and Geophysics in Washington and revised maps have appeared from time to time in the published report of the Special Committee.

In preparing the present paper three sources of data have been used, (1) the yearly reports, files and library of the *U. S. Coast and Geodetic Survey* [1924–27; 1928–55], also *Heck* [1938], *Wood* and *Heck* [1941], (2) the unpublished card index of earthquakes based on newspaper reports compiled by the late Harry Fielding Reid who prior to his death made this material available to the writer, and (3) current literature. The assistance and cooperation of the U. S. Coast and Geodetic Survey Seismological Section over the past twenty years in keeping the study up to date is most gratefully acknowledged.

Areas of tectonic activity—Figure 1 shows the location of earthquakes in the United States as reported by the U. S. Coast and Geodetic Survey through 1957. Newspaper reports not substantiated by the records of the Coast and Geodetic Survey have not been used in order to keep the data as authentic as possible. In the West Coast

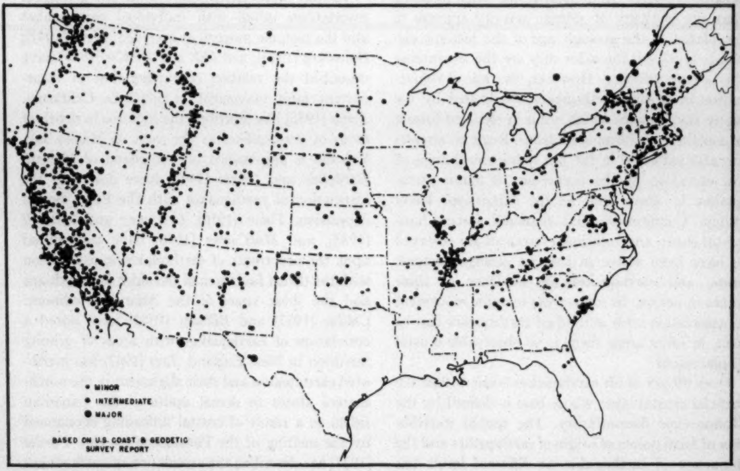

Fig. 1 – Earthquakes in the United States through 1957

area it was not feasible to plot all of the epicenters but a sufficient number are shown to define the principal areas of tectonic activity. A study of Figure 1 indicates several definite alignments and areas of marked seismic activity, the principal ones being: (1) the Puget Sound area of Washington, a known tectonic depression, (2) the California Coastal area south of Cape Mendochino, a zone of strike slip fault movement involving several faults of which the best known are the San Andreas Fault and Garlock Fault, (3) the eastern boundary of the Sierra Nevada batholith and adjacent block faulted area of the Great Basin, (4) the area around Carson City, Nevada, an area of block faulting involving both horsts and grabens as well as the buried northward extension of the Sierra Nevada batholith, (5) an alignment striking southeasterly from Puget Sound across Idaho to northern Utah which conforms in position and strike with structural axes crossing the Columbia River plateau, (6) an alignment striking southwesterly from northeast Utah to south of Carson City, Nevada, following topographic trends of the Basin and Range structure, (7) an alignment following the Rocky Mountain front zone of overthrusts in Montana which switches across to the Wasatch Mountain front in Utah to continue southward through Arizona following known faults, (8) a short alignment striking northeasterly in central Montana paralleling the Little Belt Uplift-Bowdoin Dome structural axis, (9) an alignment striking north-south in New Mexico associated with the fault boundaries of the Rio Grande basin, (10) a broad area of rather random distributed epicenters covering Wyoming, Colorado, South Dakota, Nebraska, and Kansas associated in part with known features such as the front of the southern Rocky Mountains and in part with buried basement rock structures, (11) an apparent east-southeast alignment running from the Texas Panhandle into Arkansas associated in part with the Amarillo-Wichita Uplift and in part with the Ouachita Mountain thrust zone, (12) a north-south alignment from the Tennessee-Mississippi line extending through St. Louis, Mo., in part related to known faulting and in part to unknown geologic controls, (13) an alignment striking northeasterly from the Missouri-Kentucky area across southern Indiana and Ohio, into the St. Lawrence River valley, for the most part not related to any known geologic controls except in the St. Lawrence River valley, (14) an alignment from central Alabama following the Appalachian Mountain overthrust and fold zone northeastward to southern New England, (15) a strong zone of activity striking southerly from Maine across central New England apparently related in part to intrusive granitic bodies, (16) a localized zone of activity in northern New York following the northern boundary of the Adirondack massif, (17) an alignment following the coast from the head of Chesapeake Bay to Cape Cod which parallels the structural trends in the adjacent crystalline rocks, (18) a local zone in central Virginia for the most part along an axis transverse to the local structural trends of the observable rocks, (19) a local zone in South Carolina having a similar relation to structure as observed in Virginia, and (20) a local alignment in central New England following the Connecticut River valley. There are other local zones of slight activity as in northern Florida over the Peninsula Arch, in Washington, Oregon, and California in association with the Cascade volcanic chain, in northern Illinois and southern Michigan where there is no known geologic control of the apparent alignment, and in the Alabama-Georgia-South Carolina Piedmont in association with the Piedmont fault zones.

Of equal interest are the areas which do not appear to have had earthquake activity during historic time. These include much of Oregon, eastern Nevada, southern Arizona, eastern Montana, North Dakota, Minnesota, Wisconsin, Iowa, most of Missouri, Texas, Louisiana, Kentucky, West Virginia, western Pennsylvania, southern Georgia, Alabama, Florida, and eastern North Carolina. The lack of earthquake activity in these areas cannot be related to lack of structural deformation and faulting, and it would appear therefore that local forces are more responsible for earthquakes than continent-wide regional forces. An alternate interpretation is that there is earthquake activity in these areas but of too low an intensity to be recorded instrumentally and that they are not being orally reported because of lack of population or failure of the local populace to recognize them as earthquakes. The writer, however, does not find a correlation between Figure 1 and the population density of the country and finds it difficult to believe Figure 1 represents variations in the intellectual level of the nation.

Variation in earthquake activity with time—In order to study the epicenter pattern in terms of continuity of activity, two maps are presented. Figure 2 shows epicenter locations for earthquakes prior to 1938 and Figure 3 shows epicenter posi-

tions for earthquakes since 1937. This division in time was purposely chosen in order to get an approximate even division in number of reported earthquakes. Since 1924, when the U. S. Coast and Geodetic Survey took over the responsibilities of keeping national archives on earthquakes, the number of seismological observations has markedly increased, the population has swelled, higher education is more universal, the news reporting services have greatly expanded and many previously uninhabited areas now have urban populations. As a consequence, very few earthquakes are now not reported or recorded. Prior to 1924, when the *U. S. Weather Bureau* [through 1923] kept the seismological record, the observatories were few, newspaper wire services did not have complete coverage, much of the country was essentially uninhabited and seldom visited because of poor roads, the educational level of the people and their interest in science was lower than now, and many earthquakes were never reported even when large enough to be noticeable by the local inhabitants. Prior to 1850 the situation was much worse and only major earthquakes constitute the record prior to that time.

While a 20-yr period is a rather short one in which to try and establish any significant trends, it does appear that there have been some real changes in that period. At first glance the two maps appear to be very similar, but there are points of difference. One of these is the cessation of activity indicated during the past 20 yr in the southern Idaho, northeastern Nevada, and northwestern Utah area. This area, in Figure 2, shows a well defined alignment of earthquake epicenters which cuts across the Snake River downwarp from the southern end of the Idaho batholith. Very little activity is indicated in this area in Figure 3. Another area of change is the alignment of epicenters striking to the northeast in central Montana shown in Figure 2. This alignment parallels the Little Belt Uplift-Bowdoin Dome axis. Since 1937 there appears to have been no seismic activity on this alignment. While activity in the other Rocky Mountain front states appears to have been maintained during the past 20 yr at about the same level as before, the pattern of disturbance has changed considerably. For example, Figure 2 shows a marked northeast trending alignment as a conspicuous feature in Wyoming. In Figure 3 the epicenters in the same area form two parallel alignments where only a single one was shown before. This trend is that of the main structural elements in the area, large horsts and grabens comprising the middle Rocky Mountains. The pattern and increase in activity over the last 20 yr suggests renewed rejuvenation in this area. This also is suggested by the large number of earthquakes in Montana along the Rocky Mountain front starting in 1935. In New Mexico there is a definite north-south alignment indicated for two parallel earthquake belts shown in Figure 2. One occurs in association with the Rio Grande basin in New Mexico and the other is associated with the front ranges of the southern Rocky Mountains. In Figure 3 a more disperse pattern of epicenters is shown for this area with a single southwest-northeasterly trend cutting across the state. While this trend can also be traced in the data of Figure 2, it is not nearly so pronounced. The north-south earthquake alignments follow the structural alignment of the tectonic units comprising the southern Rocky Mountains; the southwest-northeasterly trend is a cross-cutting one. In Arizona, where marked activity is shown in Figure 2 along the boundary of the Colorado Plateau and the Great Basin, only minor activity is indicated over the past 20 years. Another area of marked change in activity is the South Dakota, Nebraska, Kansas area. In Figure 2 considerable activity is indicated prior to 1938 along two parallel southwest-northeasterly trending axes and along a cross-cutting northwest-southeasterly trend. Since 1937 there has been only minor activity in this area. Similarly, a significant decrease in earthquake activity is shown in the northern Illinois, central Alabama, central New York, and northern Florida areas during the past 20 yr.

Summarizing the above it would appear that while the areas of most numerous earthquakes, as California, the Missouri-Illinois border area, New England, South Carolina, and Virginia, show continuous activity, there has been a notable decrease in activity in the northern Midcontinent area, the lower southeastern states, the Idaho, Utah, Nevada border area, and in Arizona. Only in the middle Rocky Mountain region of Wyoming does there appear to have been a significant increase in activity during the last 20 yr period. The changes in epicenter alignment without significant changes in earthquake activity, as in New Mexico and the Midcontinent area, suggest a change in stress direction. All of these observations tend to support the idea of localized stress and strain relationships determining centers of earthquake activity rather than regional, continent-wide stress conditions.

If the data for the past 34 yr, representing the period during which the U. S. Coast and Geodetic Survey has been keeping a systematic record of earthquake activity in the United States, is considered on a yearly basis in terms of which of the seismic areas outlined showed activity, a somewhat different picture is obtained. This material is summarized in Table 1, which indicates not only whether there was activity in each area but whether there were any major earthquakes (VII or greater on the Modified Mercalli scale). These

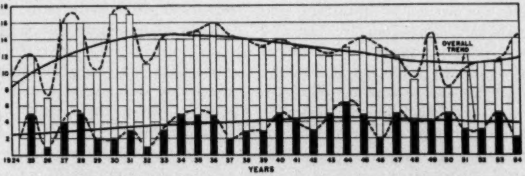

FIG. 4 – Activity in principal seismic areas in the United States as a function of time; solid bar, number of areas with major earthquakes; total bar, number of active areas

data are also presented graphically in Figure 4. The presentation used was chosen rather than one of yearly energy release since the latter would be so heavily biased by the large number of earthquakes in the California-Nevada region that variations over the rest of the country would be completely masked.

Starting with data for 1924, only nine of the 18 areas experienced earthquakes that year, and in none of them were there any earthquakes having an intensity as great as VII. The next year twelve areas were involved and in five of these there were earthquakes of intensity VII or greater. From the overall plot it is seen that there is a suggestion of a short period (3- to 5-yr) cyclic variation in activity and that this is superimposed on a much longer term period which appeared to reach a peak during the period 1931–1936, during which time an average of 14 of the 18 areas showed activity. After that time there was an overall decrease in activity reaching a minimum in the period 1951–1953 when an average of only ten of the areas showed activity. In terms of the occurrence of earthquakes having an intensity of VII or more, the variations also appear to follow the same pattern with a 3- to 5-yr cycle superimposed upon a longer term variation. A gradual increase in number of areas affected increased from about two in 1924 to four in 1944, with a decrease since. For the most part the variations in number of areas having activity and large earthquakes parallel each other from 1924 through 1941. From 1948 on, though, the two curves appear to be out of phase. The significance of these variations is not obvious, but it appears there are at least two superimposed sets of widespread regional forces in addition to those of local origin influencing the occurrence of earthquakes in the United States.

Relation to geology—While a general correlation with geologic features has been given in identifying the principal areas of earthquake activity, it is of interest to examine the relations in more detail. Figure 5 shows a plot of all earthquakes, including those from the unpublished compilation by Reid based on newspaper reports, superimposed on a map showing the main tectonic elements of the United States. This plot suggests that the tectonic forces affecting each area of activity results in earthquakes involving more than a single tectonic element in each area. The resolution of the forces present is difficult to assess since surface structural features may be either of an earlier origin or only superficial and not reflect correctly dominant structure and movement at depth where an earthquake originates. For example, surface graben, an extensional feature, may develop equally well as a result of horizontal tensional forces or as a result of vertical uplift as is seen in connection with salt dome structures. Also, in some areas there may be a combination of forces present involving both horizontal shear and uplift. To deduce correctly the tectonic significance of earthquakes associated with surface tectonic units therefore require a knowledge of many factors, most of which are usually not known. Even in seismic areas such as Southern California where the geologic relations appear to be well established [*Wood*, 1947; *Gutenberg and Richter*, 1953; *Hill and Dibblee*, 1953] and the dominant crustal movement is known to be strike slip motion along the coast with the west side of California moving northward relative to the east side, and with complementary motion at the southern terminus of the Sierra Nevada batholith such that the north side is moving westward relative to the south side, competent investigators disagree as to the stress pattern present. *Gutenberg and Richter* [1953] conclude "much of the faulting can be described in terms of a north-south compression." *Menard* [1955] on the other hand concludes the maximum compression is oriented about S 40° W.

Without going into the evidence as to which of the above two interpretations is probably correct, the present writer would like to point out that this region, while undoubtedly undergoing shear movement as a result of compression, is also subject to the vertical forces that seem to characterize all of the western states. For example, fault scarps were developed in Owens Valley on the east side of the Sierra Nevada block during the earthquake of 1872 indicating uplift of the Sierra block. Also, a glance at Figure 5 shows the occurrence of many earthquakes within the Sierra Nevada block itself suggesting rejuvenation of this tectonic arc.

A similar situation is indicated along the eastern boundary of the Great Basin where there are newly developed scarps with displacements as much as 40 feet along the Wasatch Front [*Fenneman* 1931]. *Eardley* [1951] has called attention to the alignment of earthquakes from the eastern Rocky Mountain front in Montana southward through Utah into Arizona following the zone of great trenches bordering the Rocky Mountain Colorado plateau block. Since the trench areas are bounded by high-angle gravity faults, it seems likely that the trenches are related to a common regional set of forces. From the geologic associations it appears that the boundary faults of the trenches are related to vertical uplift of the adjacent positive tectonic elements. Sedimentary loading from the adjacent highland presumably, with time, develops tilting of the trench block. This is suggested by the history of progressive although intermittent movement on the Hurricane Fault in Utah, which is one of the currently active trench boundary faults as indicated by earthquakes. According to *Gardner* [1941] the Hurricane Fault, which is about 170 mi in length, was formed in late Miocene or Pliocene time with about 8000 ft downward displacement of the western (Basin) block. Following a long period of quiet, during which all topographic

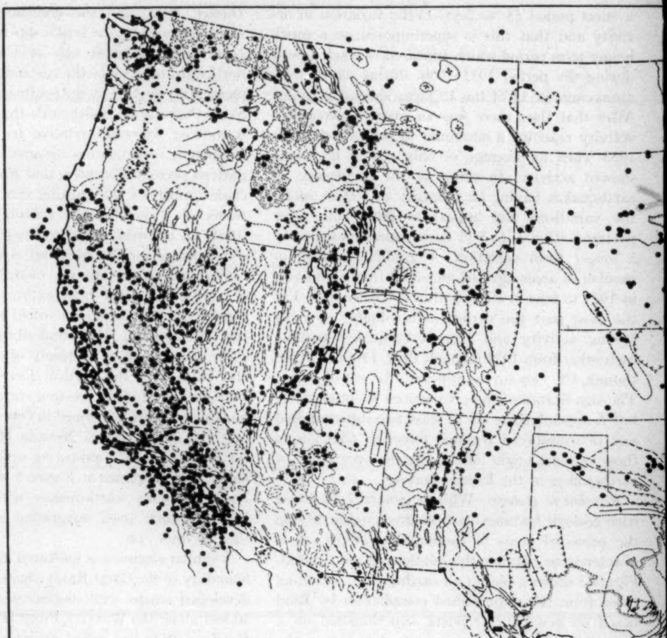

FIG. 5 – Relation of earthquake epice

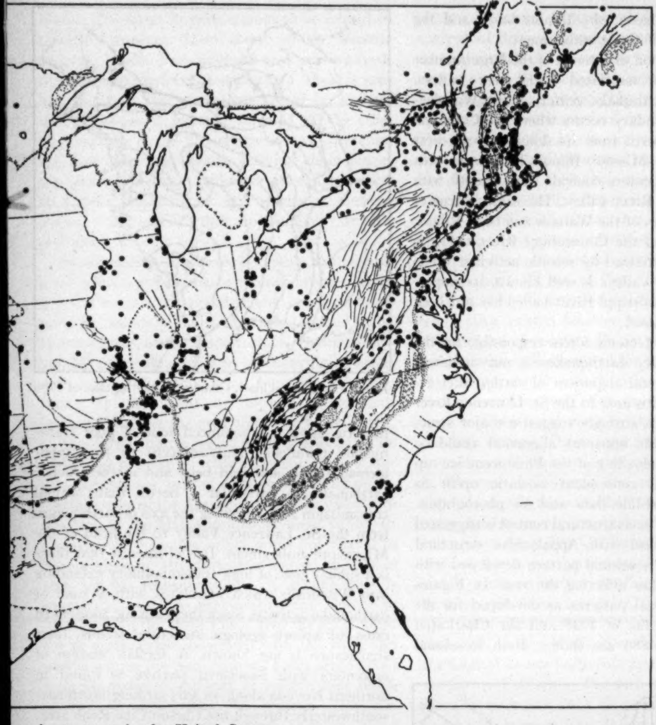
evidence of differential movement was erased, the area was covered by Quaternary basalts. Since that time there has been renewed movement with tilting and about 1000 ft relative downward displacement of the Basin block. It would be of interest to make a series of precise gravity measurements as well as triangulation and precise leveling measurements in this area over a period of time to determine which or if both blocks are undergoing movement.

Using the past recent geologic history of the western states as deduced from physiographic evidence, there has been considerable epeirogenic uplift of the whole area which from the earthquake epicenter pattern appears to be continuing. This regional movement would not be expected to develop new fractures so much as to result in considerable adjustment of crustal blocks along old fracture lines developed at different times in the geologic past under varying stress conditions. Any attempt at regional stress analysis from the epicenter pattern is therefore bound to invoke a lot of hypothetical conditions of questionable validity. The fact that most of the earthquake activity in the western states outside of California is confined to the boundary area of the Great Basin and adjacent Sierra Nevada block on the west and the Rocky Mountain-Colorado Plateau block on the east, with some activity on the east flank of the Rocky Mountain block suggests there is unit uplift of the positive blocks and possible subsidence of the intervening Basin and Range



ctonic structure in the United States

block. Local uplift is also suggested along the western boundary of the Idaho batholith and the southern boundary of the Loon Lake, Colvin, and other batholiths in the state of Washington with possible subsidence of the adjacent Columbia River basalt area. This area undoubtedly underwent considerable subsidence with the emplacement of the basalts but it is not likely that subsidence of this block is continuing now that eruption has essentially ceased, particularly in view of local uplift of such features as the Blue Mountains in the plateau area.

In the Great Plains earthquake activity is confined principally to positive tectonic elements and their boundaries, such as the Black Hills, Chadron arch, Sioux uplift, Amarillo-Wichita uplift, Abilene arch, and Sierra Grande uplift. In the middle Rocky Mountains it also is noted that the earthquakes occur in connection with the boundary of positive elements such as the Bighorn uplift, Owl Creek uplift, Wind River uplift, Sweetwater arch, and Laramie uplift. Likewise, in the central Rocky Mountains the earthquakes are associated principally with the uplifts as the Rock Spring uplift, White River uplift and Uncompahgree uplift. The intermontane Rio Grande valley in central New Mexico is the only structural basin in the Rocky Mountain block that appears to have an extensive series of earthquakes associated with it rather than with the adjoining positive blocks. Other structural basins showing marked earthquake activity are the Puget Sound depression, the Anadarko basin, the Illinois basin and the head of the Gulf Coast embayment.

One observation of interest is the large number of earthquakes associated with river valleys. The marked earthquake center on the Washington-Oregon boundary occurs where the Columbia River swings north from its dominant east-west path. In the Missouri-Illinois-Tennessee area earthquake epicenters coincide very closely with the Mississippi River valley. The same is true of the lower reaches of the Wabash and Ohio Rivers. In New England the Connecticut River valley is similarly characterized by seismic activity. While fault control of valleys is well known, its importance in the Mississippi River valley has not been generally recognized.

Although the tectonic forces responsible for the Mississippi Valley earthquakes is not definitely known, the general alignment of earthquakes extending out of this area to the St. Lawrence River valley in Canada strongly suggest a major structural break. This apparent alignment could be related to the unloading of the Pleistocene ice cap in Canada and consequent isostatic uplift as evinced by level-line data and air photographs. That there may be a structural control is suggested by the parallelism with Appalachian structural trends and the isoseismal pattern developed with major earthquakes affecting the area. In Figures 6 and 7 isoseismal patterns as developed for the Quebec earthquake of 1925 and the Charleston earthquake of 1886 are shown. Both isoseismal patterns show a pronounced zone of poor transmission paralleling and adjacent to the Appalachian thrust and fold belt, and in the Quebec earthquake in particular a better than normal transmission zone following the axis of earthquakes from the St. Lawrence Valley to the head of the Mississippi embayment. It is of interest that there is a similar zone of high transmissibility extending into Wisconsin which correlates with a zone of earthquake activity. Since these seismic zones both cross-cut known geologic structural trends, their significance is not known. A similar relation of epicenters with isoseismal pattern is found in northern Nevada along an axis striking northeast-southwesterly through the Carson City-Reno area.

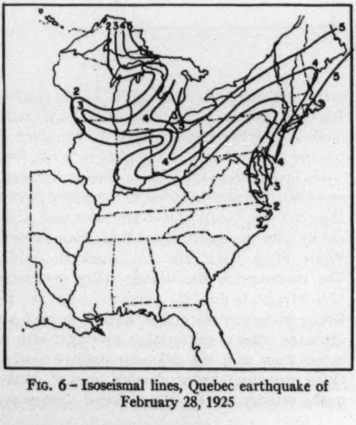


FIG. 6 - Isoseismal lines, Quebec earthquake of February 28, 1925

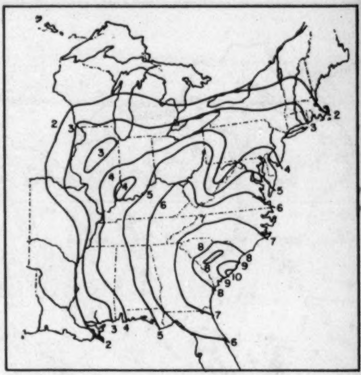

FIG. 7 - Isoseismal lines, Charleston earthquake of 1886

In the Appalachian region the fact that both the Piedmont shear zone and the belt of overthrusts and folds show continuing seismic activity as well as the development of cross structure earthquake alignments as in South Carolina suggests regional uplift, shearing, and warping. This appears to be substantiated by basement structures such as the Cape Fear arch and Salisbury embayment beneath the Coastal Plain, as well as the surface geologic features.

In the New England area activity is again noted in the boundary zone of a known tectonic element, the Adirondack massif. Earthquakes also occur in connection with the Taconic Fault, along the boundary of the Narragansett Basin, in the Boston Basin, in association with the Connecticut River and along on two and possibly three alignments in the crystalline rock area of New Hampshire and

Maine. The latter in part appears to be related to granitic intrusives. Since nearly all the tectonic elements in the New England area are involved, it would appear that the region as a whole is subject to stress. One cause here would be regional uplift because of isostatic rebound of the crust after melting of the Pleistocene ice cap. However, the fact that earthquake activity characterizes the entire Atlantic seaboard strongly suggest epeirogenic movement and perhaps shearing stresses throughout the Appalachian tectonic province.

To summarize the above, it appears that epeirogenic uplift is in progress over much of the country giving rise to earthquakes along older fractures and the boundary faults of major tectonic units. In some areas, as the western states, entire physiographic provinces appear to be behaving as a unit with little disturbance away from the boundary faults; in other areas, as the eastern seaboard, faults throughout the area appear to be activated. In the stable interior region activity appears to be associated principally with basement areas of uplift. There is one 'belt' of earthquakes which parallels the strike of the Appalachians and crosses from the head of the Mississippi embayment to the St. Lawrence River valley which while not related to known geologic structure does follow an axis of high seismic transmissibility. A similar zone is suggested running east-west from Iowa to Michigan. In the West Coast area the great number of earthquakes associated with the strike-slip movement on the San Andreas Fault and related systems makes it difficult to resolve how much epeirogenic uplift may be present. However, activity within the Sierra Nevada block and along its eastern boundary strongly suggest this unit is rising. Only in the Puget Sound depression, the Anadarko Basin and the Rio Grande valley of New Mexico is there any suggestion of local activity suggesting active subsidence outside of the Great Basin.

Focal depth relationships—In the introduction it was stated that most earthquakes in the United States originate in the crustal layer defined by the terrestrial section lying above the Mohorovicic discontinuity. This on the average is at a depth of about 35 km if seismic-blast studies of crustal thickness are accepted. If gravitational data are evaluated in terms of variations in crustal structure under the Airy theory of isostasy using auxiliary seismic data in both the oceanic and continental areas for control purposes, a somewhat different picture of crustal structure is obtained. Such an analysis of Bouguer gravity anomalies shows that the eastern half of the country has a crustal thickness of about 35 kms and the western half a mean value approaching 50 km. The mountain zones in both areas are characterized by local thickening. This picture of the continental crust is essentially the same as that developed recently by *Press* and *Ewing* [1957] from their analyses of Rayleigh wave phase velocity dispersion in the United States from distant earthquakes. In view of these apparent variations in crustal thickness and the fact that most continental earthquakes originate within about 30 km of the surface, the writer felt it would be instructive to see if any systematic relationship existed between the focal depth and thickness of the crust. To investigate this, the focal depths were computed for those earthquakes that were unusual enough either in terms of intensity on widespread effect to warrant the preparation of isoseismal maps by the U. S. Coast and Geodetic Survey. These depths were first grouped according to the areas of seismicity outlined earlier. In the case of California the area was first subdivided into sub-areas which it was thought might have differences on the basis of regional differences in geology. The California coastal area was divided into a northern sector, a central sector, and a southern sector. Southern California was further divided into two parts, the Mohave Desert area immediately south of the Sierra Nevada batholith, and the Mexican border area adjacent to the Gulf of Lower California and including northern Lower California. The area east of the Sierra Nevada batholith in California was considered along with western Nevada since both are in the same geologic province. For similar geologic reasons data for southern Quebec and Ontario were considered in a group that also includes northern New York. All of the New England states were considered as a unit. Another area considered as a unit was southeastern Missouri, southern Illinois and Indiana, western Tennessee and Kentucky, northern Mississippi and Arkansas.

The method of computing focal depth used is that based on the gravitational acceleration equivalents of the Modified Mercalli scale value at the epicenter and the epicentral distance to the I–II isoseismal contour. Since, as shown in Figures 6 and 7, the isoseismal pattern is usually far from regular, mean distance values were used. While the resulting focal-depth determinations at best are only approximations, the values obtained are very instructive and appear to give a real indication of variations in focal depth within and between areas. In general the depths obtained are somewhat greater than those determined from instrumental recordings, but not significantly different.

In some areas the depths obtained are remarkedly consistent. In other cases there are big differences, as in New England where there appears to be two distinct levels of activity: one at about 90 km and the other at 26 km. Here the explanation for the two levels of activity is suggested by the geologic associations. Earthquakes having a deep focus appear to be associated with granitic intrusive bodies and those at shallow depth with possible fracture zones. While New England represents an extreme case as regards separation of focal-depth levels, in other areas where the spread in levels is less pronounced, there is also a tendency for earthquakes to occur at discrete depths rather than on a random basis. In Table 2 the results are summarized as related to geographic distribution, and arranged so as to progress along strike of the various geologic provinces. In Table 3 the results are summarized as related to geologic provinces as a whole.

As the depth characterized with the greatest frequency of occurrence is also of interest, the data are summarized from this viewpoint in Table 4.

California Coastal area about equal occurrences at	31 and 17
Puget Sound	33

From a study of these tables it appears four depths of earthquake origin are dominant: roughly 15–25 km, 30–35 km, 40–45 km, and 60–65 km. In any one area no more than three depths of origin occur. In general, coastal areas have shallower depths of origin for earthquakes than the continental interior. However, this is not an infallible rule since the Charleston, S. C., earthquake of 1866 had a deeper than normal focal depth for the Appalachian region.

It is seen that each seismic area has a distinctive depth pattern of earthquakes which may or may not extend into an adjacent seismic area. The distribution characteristic of the Pacific and western states, and which is not found elsewhere involves three depths: 15–20 km, 30–35 km, and 40–45 km. Activity is dominant in the shallow and intermediate zones along the Pacific Coast, but only at the 30-km level in the adjoining Great Basin area of block faulted structure. In the Rocky Mountains the characteristic depths are 45 km and 65 km with no marked preference as to frequence of occurrence. It may be significant that the deep focal depths here occur in the area of apparent maximum crustal thickness. In the stable shield area of the Midcontinent there are three depths of occurrence, 20–25 km, 40–45 km and 60 km. The level of greatest activity appears to be the 40- to 45-km zone. Except for the very deep earthquakes noted in New England in association with granite intrusions and the Charleston earthquake, a shallow focus depth of about 25 km characterizes the entire eastern seaboard. In the Appalachian Mountains proper the limited data suggest 43 and 26 km as characteristic values for this region.

From this admittedly qualitative study, which in the writer's opinion is the only kind justified in the present light of knowledge and available data, it appears that crustal thickness is somehow connected to the predominant depth of earthquake occurrence in the country. The thicker the crust, the deeper the depth of earthquake occurrence. In all areas the depth of predominant frequency appears to be somewhat above the base of the crustal layer. Where several discrete depths of earthquake occurrence characterize an area, the upper one never appears to be shallower than 12 km and usually is around 20 km. The deepest zone, except for the possible special case of granitic intrusives, appears to be about 60–65 km and this in all cases appears to be associated with the mantle rocks beneath the crust.

The implications of the above distribution and crustal relationships are not clear except in that crustal thickness is an apparent controlling factor. One possibility is that discrete changes in crustal rigidity such as are indicated by changes in crustal velocity associated with the Conrad and Mohorovicic discontinuities might influence the development of tensional and compressional strains in the boundary areas of a series of flexed crustal plates. The investigation of these relationships is being pursued further.

General remarks on observations—To try to explain the origin of the forces responsible for the observed earthquakes, their spatial distribution and variations in seismic activity with time is too hazardous an undertaking in view of present limited knowledge. However, a few remarks are justified concerning the relation of the observed activity to such factors as degree of isostatic equilibrium and variations in crustal structure both of which might play a role in causing earthquakes.

Relation of seismic activity to areas of isostatic unbalance—Since recent epeirogenic uplift appears to be a real phenomena over most of the western states and to a lesser extent in the Appalachian Mountain area from geologic data, there should be some independent indication other than earthquake activity as to whether this uplift still may be active. One approach to the problem is through a study of gravity anomalies. The Appalachian Mountain area is one of the seismic areas that is known from the gravity anomalies to be definitely out of isostatic equilibrium. The isostatic anomalies here indicate a marked deficiency in mass at depth which suggests a root much larger than is required to support the surface topography. Such an area could be expected to be subject to stresses leading to epeirogenic uplift. The adjacent Piedmont area on the other hand is an area of excess gravitational attraction. This suggests that this area in past geologic time was subject to marked uplift and that subsequent erosion of the surface arch created resulted in crustal thinning. Such a condition should induce forces leading to subsidence in order to establish isostatic equilibrium. The various summit peneplain surfaces in the Appalachian Mountain area confirm a history of continuing uplift in that area over a long period of time. The fact that the axis of Triassic arching in the Piedmont corresponds to that of the gravity maximum [*Woollard*, 1948] tends to confirm the idea of past uplift in that area. However, instead of subsequent subsidence recent studies of the basement configuration beneath the Coastal Plain [*Ewing* and others 1950] and [*Woollard* and others 1957] suggests considerable crustal warping not related to the gravity-anomaly pattern. In this connection it should be noted that the areas of current earthquake activity in the Piedmont-Coastal Plain region, particularly South Carolina and Virginia, do not correspond in position to the areas of basement warping. Further, only one minor earthquake has been reported over the positive Cape Fear arch although there is an alignment of earthquakes along the eastern boundary of the negative Salisbury Embayment (see Fig. 5).

While there are isostatic anomalies associated with many of the seismically active tectonic elements such as the Amarillo-Wichita uplift, Black Hills, Bighorn Mountains, and Rock Springs uplift, these are all areas of gravity maxima and appear to be uncompensated loads supported in large measure by the strength of the crust. Also, the geologic evidence indicates these areas are probably rising rather than subsiding. The only marked seismic area that is isostatically out of balance that appears to be sinking is the Puget Sound trough in Washington. This is an area with a pronounced gravity minimum that theoretically should be trying to rise rather than sink as it appears to have been doing. The gravitational evidence therefore cannot be used to make a firm case for either uplift or subsidence, and certainly there are many areas of marked local isostatic anomalies with which no earthquakes are identified. One such is the positive gravity anomaly area extending about 1000 mi southward from Lake Superior which is associated in part at least with synclinal structure and intruded basaltic lavas of Precambrian age. In the areas of greatest seismic activity, namely, California and Nevada as well as the area of marked recent epeirogenic uplift, the Colorado Plateau, isostatic compensation on the whole appears to be fairly well established with only local departures which appear to be associated with included structural units such as the Zuni and Defiance uplifts and the San Juan and Green River basins. The details on these gravity relations are not included here since they are being published by the writer elsewhere. The significant point is that current seismic activity cannot be related directly to the degree with which isostasy prevails.

Relationship of seismic activity to variations in crustal thickness—The relationship of earthquake focal depth to crustal structure has already been discussed. In this section the general problem of whether there is any correlation in terms of activity will be considered.

Where the crust is thick with presumably a high moment of inertia and greater rigidity than elsewhere, there may be an appreciable time lag in achieving hydrodynamic stability for changes in surface elevation brought about by erosion. Such a time lag would be expected to develop epeirogenic stresses leading to vertical uplift and associated earthquakes. It should also lead to negative isostatic gravity anomalies such as are observed in the Appalachian Mountains. The absence of any regional negative isostatic anomaly in association with an area of uplift as the Colorado Plateau implies equilibrium conditions with crustal thickening commensurate with the elevation. From studies of Bouguer gravity anomaly values by the writer this appears to be the case. However, seismic explosive blast studies by *Tuve* and *Tatel* [1955] in the Colorado Plateau as well as unpublished studies by other investigators in this area, indicate a crustal thickness considerably less than would be expected for equilibrium conditions. In fact, the thickness found is even less than that observed in the interior stable shield area of Minnesota and Wisconsin having a low elevation. It should be noted though that regional negative isostatic gravity anomalies in this part of the shield area do indicate a thicker-than-normal crust. This would suggest epeirogenic uplift stress in the area. However, this is an area essentially devoid of earthquakes. It is, however, an area that has been subject to continuous although perhaps intermittent uplift since early Paleozoic time. To explain the apparently anomalous relations it must be postulated that the rate of stress accumulation leading to uplift in the shield and accompanying earthquake activity is very slow. Presumably, when activity does take place it is pronounced and possibly similar to what is now being observed in the Missouri-Illinois-Arkansas-Tennessee border region which also lies in the stable shield area at the southern end of the Ozark uplift. Some of the biggest earthquakes in American history have occurred in this supposedly stable area.

Coming back to the Colorado Plateau area, it is of interest that seismic measurement of crustal thickness in other plateau areas based on explosive blasts give values no greater than observed in the lowlands and in all cases the values are incompatible with gravitational data, which suggest a thick crust. This has led *Hess* [1955] to postulate that the plateaus are rejuvenated through serpentenization of the subcrustal mantle rocks of ultrabasic composition. This process would result in subcrustal expansion forcing up the overlying crustal layer with no change in its thickness, explain the rejuvenation of plateaus, the associated earthquake activity and also satisfy both the Bouguer and isostatic gravity anomalies. While this is a very attractive hypothesis, it cannot be said to be proved. Cognizance also must be taken of the recent study by *Press* and *Ewing* [1957] using the velocity dispersion of Rayleigh waves as a means of determining crustal thickness. This technique gives values of crustal thickness in substantial agreement with that which the writer has computed from gravitational data. It leaves the problem of epeirogenic uplift of the plateaus and associated earthquake activity in the same indeterminate state as was reached from the study of gravity data alone.

Away from the plateaus in the lowlands and older tectonic areas, as the Appalachian Mountains, the observed values of crustal thickness from explosive blasts agree with the indications of the gravity data and the implications as to possible causes of tectonic activity in these areas. It therefore appears that there is no unique relation between variations in crustal thickness and degree of seismic activity.

Relation to theories of mountain building—While many theories have been advanced pertaining to mountain building [see *Eardley*, 1957, for a good review] they can be divided into three groups that might be expected to give a continuing history of associated seismic activity. One of these is represented by Hess's theory for crustal uplift because of periodic subcrustal expansion and contraction. This has already been commented upon. Another would be that of convection currents as proposed by *Griggs* [1939]. The third is the theory proposed by *Wilson* [1954] involving the formation of primary and secondary tectonic arcs with associated fracture zones through crustal contraction.

As the island arcs and associated seismic zones and gravity minima are used as pertinent evidence to support both Grigg's convection-current theory and Wilson's primary-secondary orogenic mountain zones, these relationships cannot be said to be proof for either theory. The identification of world serpentine belts with areas of orogenic activity and the island arcs by *Hess* [1937] however does appear to constitute evidence that these two physiographic features have something in common, and that the island arcs may represent a stage in the orogenic development of a mountain range. A significant and different feature of Wilson's theory is the development of opposing arc systems and associated connecting fracture zones. The writer would expect some indications of seismic activity along these associated fracture belts if they are genetically related to the orogenic mountain arcs. Such activity is conspicuously absent, which is surprising in view of the number of such postulated zones ringing the shield area on the east, south, and west. Further, except for the Appalachian Mountain area, the seismic belts of activity do not conform to the tectonic grain of the postulated orogenic mountain arcs as they do with the oceanic island arcs. While it can be argued that it should not be expected that early stress patterns as seen in the island arcs should persist in their later continental mountain counterparts, it seems strange that a single range of mountains as old as the Appalachians should preserve a relation of tectonic activity to structural pattern while much younger tectonic provinces of greater structural derangement do not show such a relationship. Perhaps in Triassic time the Appalachian earthquake activity followed the graben fault boundaries rather than the zone of thrusts similar to the relations observed with the trenches bordering the Rocky Mountain block today. The problem cannot be unequivocally answered, but it does appear there is little seismic evidence that can be offered in support of any one theory of mountain building being any more probable than another.

There is one bit of evidence though in connection with the Appalachian Mountains that does appear significant. This has to do with the question of whether the Appalachian Mountain system is continuous beneath the Mississippi embayment with the Ouachita Mountains of the same general age in Arkansas and Oklahoma. It is noted from Figure 5 that there is no continuous zone of earthquakes connecting the two and that the Appalachian zone of epicenters continues beneath the Coastal Plain along the same general northeast-southwesterly strike until they die out. These observations suggest that the two mountain systems are independent, although contemporaneous, and that they intersect with a 'T' relationship somewhere beneath the Mississippi-Alabama Coastal Plain.

Gravity Survey of Ogden Valley in the Wasatch Mountains, North Central Utah

SAMUEL W. STEWART

Abstract—Ogden Valley is a northwest-trending valley in the Wasatch Mountains of north central Utah. From geologic investigations it is inferred that Ogden Valley is structurally controlled by normal faults along both the northeast and southwest margins. Gravity measurements in the valley indicate a fault with about 2000 ft of vertical displacement along the west margin of the valley. A fault with at least 1000 ft of vertical displacement is postulated along the east margin of the valley, and a smaller, buried fault is postulated within the valley. The maximum thickness of Cenozoic sediments and sedimentary rocks in the valley is estimated to be about 5000 ft.

Introduction—Ogden Valley, in Weber County, Utah, is a back valley lying about five miles east of the Wasatch front in north central Utah (Fig. 1). Its area of about 40 sq mi makes it one of the largest of the back valleys in the north central Wasatch Mountains. The valley trends northwesterly, slightly oblique to the north northwest strike of the Wasatch Mountains. It is completely enclosed on all sides except for one narrow drainage outlet, the Ogden River.

Ogden Valley is usually referred to as a 'structural trough,' implying that its present disposition is due primarily to normal faulting along its northeastern and southwestern margins, or to faulting along one margin only. However, none of the geologic maps of the area, from that of *Gilbert* [1890, p. 352] to that of *Lofgren* [1955, p. 70], indicates the location or trend of these faults.

A gravity survey was made to determine the probable presence or absence of these faults, and to delineate other major structural trends that may exist in the valley. It was also hoped that this investigation would aid in the study of similar structures, and be useful in studies of groundwater problems in the valley.

Geologic setting—The general geology of the Wasatch Mountain region has been reported in many early studies, most notable of which are those of *King* [1878] and *Gilbert* [1890]. *Blackwelder* [1910] first reported on the complexities of the thrust structures in the vicinity of Ogden Canyon. *Eardley* [1944] published a comprehensive report on the stratigraphy, structure, and physiography of the north central Wasatch, with special emphasis on the evolution of the Laramide and later structures. The U. S. Geological Survey, in cooperation with the State of Utah, has studied the unconsolidated sediments of Ogden Valley with emphasis on their hydrologic aspects [*Leggette* and *Taylor*, 1937; *Lofgren*, 1955; *Thomas*, 1945].

Except for a few Paleozoic sedimentary rocks cropping out along the west margin, Ogden Valley is enclosed on the north, east, and west by the Precambrian and Cambrian metasedimentary rocks of the Wasatch Mountains. These mountains rise as much as 4000 ft above the valley floor. Ogden Valley is separated from Morgan Valley to the south by a low, rolling ridge of stratified tuffs and marls of Tertiary age.

The present physiographic expression of Ogden Valley, of Morgan Valley to the south, and Cache Valley to the north is due primarily to late Laramide broad folding that trends north-south, and post-Laramide Basin-and-Range type normal faulting. *Schick* [1955] has shown the existence of normal faults younger than early Oligocene along the east side of Morgan Valley. *Adamson* and others [1955, p. 22] state that in Cache Valley "Post-Salt Lake group high-angle faults seem to parallel the mountain fronts. . . ." The Salt Lake formation is assigned a Pliocene (?) age. *Lofgren* 1955, p. 83] summarizes the evidence for normal faulting in Ogden Valley as follows: "Whereas the principal structure of Ogden Valley is due to folding, faulting, and general downwarping, which are known to have taken place mainly in Tertiary time, . . . fault scarps showing recent displacement are recognized in the valley. Along the west margin of the valley and paralleling the general trend of the structural trough, a scarp having several tens of feet of displacement is clearly defined. Although this scarp is somewhat modified by erosion, it is recent enough to be traceable in relief for several miles, and is evident along the base of the mountain front west of Liberty. Along this fault line arise several springs, which in the area west of Liberty yield sizable quantities of cold water of good quality. South and east of the large Liberty Springs, a series of small springs follows the base of the fault scarp. . . ." *Thomas* [1945,

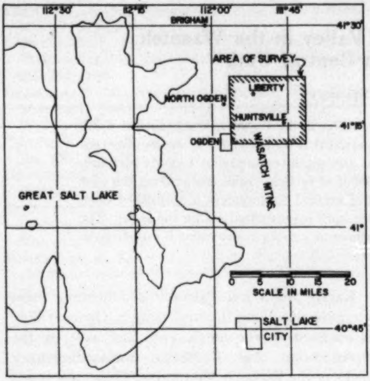

FIG. 1 – Index map of north central Wasatch Mountain region

p. 9], in correlating well logs in Ogden Valley, found evidence of displacement of about 25 ft within the unconsolidated sediments of the valley. He states that this displacement may be due "... perhaps because of displacement on a fault along the west margin of Ogden Valley, perhaps merely because of inaccuracies of the driller's logs."

Only one reference describing faulting along the eastern margin of Ogden Valley was found in the literature. In this reference *Gilbert* [1928, p. 57] states: "On the eastern margin of the valley there is a fault with throw to the southwest. . . ." Although the normal faulting of basin-and-range type throughout the north central Wasatch region is believed to range in age from late Eocene to Recent, it all seems to be related to a single subcrustal force active to the present time.

Field methods—One hundred gravity stations were established in Ogden Valley and immediately adjacent areas during the winter months of 1955–1956. A Worden gravimeter having a sensitivity of 0.09951 mgal per scale division was used. A standard looping method of making gravity observations was employed whereby a gravity base station was occupied three or more times a day for purposes of gravimeter drift control, and subsidiary drift checks were made on a few other stations throughout the day. In addition, repeat gravity observations were regularly made at other stations established earlier in the survey. These repeat readings show that the observed values of gravity are accurate to 0.02 mgal.

The survey was tied to the U. S. Coast and Geodetic Survey Pendulum Station 49 in Salt Lake City, Utah [*Duerksen*, 1949].

Elevation control was obtained primarily by means of bench marks and other points of known elevation found on the U. S. Geological Survey topographic quadrangle maps used in the survey. Eight elevations were interpolated from the contour lines on the topographic maps, and are believed to be accurate within four feet in the flat areas of the valley and within ten feet in the more mountainous areas.

A plane table and alidade was used to obtain elevations along the eastern margin of the valley. These elevations are accurate within four feet.

Reduction and presentation of data—Readings of observed gravity were corrected for drift of the gravimeter, for the latitude and elevation of each station, and for terrain effects. The latitude correction for each gravity station, based upon the international gravity formula of 1930, was obtained from tables of *Swick* [1942, pp. 61–63]. An elevation correction of 0.06 mgal per foot was used, corresponding to an average rock density of 2.67 gms per cm^3. Terrain corrections out to a radial distance of 5.2 mi from each gravity station were made using the U. S. Coast and Geodetic Survey tables [*Swick*, 1942, p. 68].

One thousand mgals have been added to the Bouguer values so that a gravity map with all positive numbers can be presented. By subtracting 1000 mgal from the values on the gravity map or profiles the Bouguer anomalies, corrected for terrain to the radial distance of 5.2 mi, may be obtained.

The relative gravity at each station is believed accurate to 0.3 mgal.

The Bouguer gravity field is shown on the gravity contour map (Fig. 2) in relation to the surface geology. The exposed rock types, generalized from the maps of *Eardley* [1944] and *Lofgren* [1955], are shown as Quaternary alluvium, Tertiary tuff and conglomerate, and Paleozoic and Precambrian bedrock. For the purposes of this gravity survey, bedrock is defined as representing the more dense pre-Cenozoic sedimentary and metasedimentary rocks, and does not include the less dense Cenozoic sedimentary rocks. Regional gravity effects, to be discussed below, are not removed from this map.

Two gravity and geologic profiles, whose positions are shown in Figure 2, are presented in Figures 3 and 4. After an assumed linear regional gradient was removed from the profiles, they were quantitatively examined to determine the most reasonable bedrock-Cenozoic interface that could account for the residual anomaly. A graticule, designed by D. C. Skeels [*Dobrin*, 1952, p. 98] was used to make the analysis. Because the inferred geologic profile is not infinitely long in the dimension perpendicular to the plane of the profile, it was necessary to apply an end correction factor [*Nettleton*, 1940, p. 117] to all the points along the profile where the gravity effect was determined.

In choosing a suitable density contrast between the bedrock and the Cenozoic sedimentary rocks, it was necessary to consider the densities of the bedrock, of the alluvium, and of the Tertiary tuffs and marls, as well as the compaction of the unconsolidated valley sediments with depth. Lists of densities for the common rock types are plentiful in the literature. For the Precambrian metasedimentary rocks that constitute the main part of the bedrock, an average density of 2.7 gm per cm^3 was assumed based on data of *Heiland* [1946, p. 72–84]. Similarly, a density of 2.2 gm per cm^3 was assumed for the unconsolidated valley sediments. This figure takes into account the compaction of the sediments to a depth of a few thousand feet, and the fact that they are, for the most part, water saturated.

In determining an average density for the Tertiary tuffs and marls, no suitable data were found in the literature. As an alternative, specimens of the tuff were collected from three outcrops south of Ogden Valley, and their density determined. The water-saturated densities of the tuff were found to range from 1.39 to 2.25 gm per cm^3; the average was about 2.10 gm per cm^3. The densities of these tuffs and marls will certainly increase with depth, owing to compaction.

Because of the similar densities of the unconsolidated valley sediments and the Tertiary tuffs and marls the writer feels secure in combining these two rock types for the purpose of analyzing the gravity data. These combined rock types are assigned an average density of 2.2 gm per cm^3. The density contrast between the pre-Cenozoic bedrock and the Cenozoic sediments and sedimentary rocks is about 0.5 gm per cm^3, and this figure is used in the graticule analysis. The primary features of the Bouguer gravity anomaly are therefore attributable to the primary density contrast existing between the pre-Cenozoic metasedimentary rocks and the Cenozoic sedimentary rocks.

GEOLOGIC INTERPRETATION OF THE DATA

General features—The gravity anomaly (Fig. 2) comprises a closed gravity low centering over the sedimentary rocks of the valley, and rapidly increasing gravity values along the bedrock margins of the northeastern and southwestern parts of the valley. These steep gravity gradients indicate the existence of a steep bedrock-Cenozoic interface beneath the valley.

The northwestern and southeastern margins of the valley are characterized by comparatively low gravity gradients. These indicate a gentle rise of the bedrock surface beneath the valley to the places where it crops out around the valley. There is no geological or geophysical evidence for the existence of faults or other steep bedrock slopes along the northwestern and southeastern margins of the valley.

The fact that values of the gravity along the west side of the valley are about 15 mgal higher than those along the east side of the valley indicates the existence of a regional gradient on which the Ogden Valley anomaly is superposed. From Figures 3 and 4 the gradient is seen to decrease to the northeast at a rate of about 1.3 mgal per mile. This gradient is too large to be caused entirely by distant topographic effects, and must have a more profound cause.

It is possible that this regional gradient in the part of the mountains surveyed indicates a regional thickening of a lighter density crustal material underlying the Wasatch Mountains in Utah. It could also indicate horizontal variations of density within the Precambrian and Paleozoic rocks. No definite conclusion can be reached on the basis of this survey.

In the quantitative analysis of profiles A-A′ and B-B′ this regional gradient is subtracted from the Bouguer anomaly values, and the residual anomaly analyzed.

Analysis with graticule—The positions of profiles A-A′ and B-B′ were chosen for the quantitative graticule analysis in the hope that they would give the most meaningful interpretation of the pre-Cenozoic configuration beneath the valley. Because of the few stations established on bedrock along the northeast margin of the valley, it was necessary to take the profiles virtually next to each other in this region, and then to skew them apart in the south-

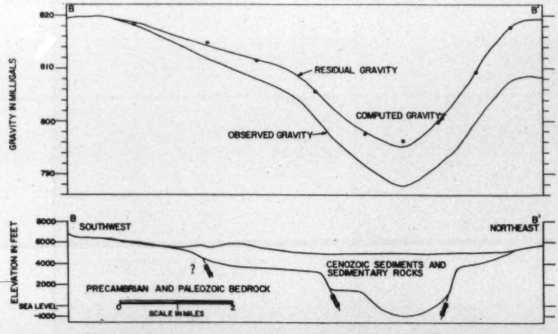

FIG. 4 – Geology and gravity anomaly along Profile B-B′

west part of the valley. The fact that profile B-B′ is not quite perpendicular to the gravity contours should not have a major effect upon the interpretation.

Profile A-A′ is best interpreted by assuming two faults along the southwest side of the valley and one fault along the northeast side. The westernmost fault in section A-A′ is exposed at the surface, so there is no doubt of its existence. The gravity analysis indicates that it has a vertical displacement of about 2000 ft. About 2000 ft east of this fault, and buried beneath about 2000 ft of Cenozoic sediments and sedimentary rocks, another fault having a displacement of about 1500 ft is postulated. This buried fault also manifests itself across profile B-B′.

The fault postulated along the east margin of the valley in profile A-A′ is buried beneath approximately 1500 ft of Cenozoic sedimentary rocks, and has a vertical displacement of about 1500 ft. The total vertical displacement along the two western faults in profile A-A′ is about 3500 ft.

The interpretation of profile B-B′ is similar. The westernmost fault in profile A-A′ is not, however, definitely indicated by the gravity data along profile B-B′. Instead, there is only a slight but noticeable thickening of the Cenozoic sedimentary rocks in the western third of profile B-B′. If this fault continues southward to profile B-B′ its vertical displacement in the region must be small, probably less than 500 ft. For if a normal fault of major proportions does exist nearly perpendicular to the plane of profile B-B′ in this area it would appear in the gravity data because the less dense

Cenozoic sedimentary rocks would be in fault contact with the more dense bedrock. It is concluded that the displacement of this marginal fault decreases greatly from profile A-A′ to profile B-B′. Because the existence of this marginal fault in the latter profile is only inferred, and neither proved nor disproved by the gravity data, its position is indicated with a question mark in Figures 2 and 4.

The buried fault east of the westernmost fault in profile A-A′ has already been mentioned as extending southeastward to profile B-B′. The easternmost fault in profile B-B′, similar to that in A-A′, is buried beneath about 1000 ft of Cenozoic sediments and sedimentary rocks, and has a vertical displacement of about 2000 ft. The assumed density contrast of 0.5 gm per cm^3 used in the graticule analysis indicates that the deepest accumulation of Cenozoic sedimentary rocks in the valley is about 5500 ft. It may be greater or less than this, depending on whether the true density contrast is less or greater than that assumed.

Slightly west of the deepest part of the Cenozoic sedimentary rocks in both profiles an abrupt change of the bedrock slope is indicated by the quantitative interpretation of the gravity profiles. This sharp change in slope may be the result of faulting, of erosional processes that occurred before deposition of the Cenozoic sedimentary rocks, of the broad north-south folding known to have occurred in this region in early Tertiary time [*Eardley*, 1951, p. 325–336], or a combination of these processes.

The positions and displacements of the faults and the sharp change of bedrock slope noted above in profile B-B′ correlate well with those in A-A′. The vertical projection to the surface of the upper edge of the footwall portion of each fault, or the upper edge of the sharp change in bedrock slope, is indicated by × along profiles A-A′ and B-B′ in Figure 2.

Conclusion—With the assumptions made in the analysis of the gravity profiles it would be difficult to make a greatly different and still geologically reasonable interpretation of the gravity data. It would be possible to substitute a series of step faults of small individual displacements for the large normal faults of thousands of feet of displacement postulated along both margins of the valley, but the writer feels it would be misleading to attempt to force from the data an interpretation that is not warranted by the available geophysical or geological evidence.

The 5000-ft thickness of Cenozoic sediments and sedimentary rocks in Ogden Valley is much greater than one might expect for an enclosed valley of only five to seven miles maximum width. This great thickness and the large displacements along the normal faults forming this graben structure are of such magnitude that they should be taken into consideration in future studies of the evolution of the Basin and Range Province in general, and the Wasatch region in particular.

Letter to the Editor

Photogrammetric Flow Measurements on Antarctic Glaciers

During 1957 measurements of the rate of ice flow were made by conventional ground survey methods along several stretches of coast within 50 mi of the main base of the Australian National Antarctic Research Expeditions. It seemed highly desirable to measure also the velocity of certain fast-moving ice streams which were situated at greater distances from the base, but for logistic reasons it was not possible to put ground parties in these areas, which in any case presented great difficulties of access and control for ground survey.

Measurements made by triangulation on a small glacier tongue suggested that the movement of the big ice streams was probably sufficiently rapid to permit measurements to be made by aerial photogrammetry over a period of a few months. The most important prerequisites were fixed control points and ground marks on the moving ice.

Oblique photographs taken earlier showed numerous rock outcrops and skerries along the coast and it was found that fixed rock control points could be located for each of the glaciers (the Jelbart Glacier in MacRobertson Land and the Dovers and Hoseason Glaciers in Kemp Land). Moreover, there was photographic evidence that configuration of crevasse patterns at the seaward extremities of these glaciers did not change over the period of one year, so that crevasses or melt channels could be utilized as ground marks.

Photographic runs, using only the vertical camera of a trimetrogon installation, were planned so that rock islands and outcrops would be included, and the first flights were made in early August 1957. A D. H. Beaver aircraft was used and the runs were made at a true altitude of 10,000 ft, thus giving a scale of 1:20,000 on photographs taken with a six-inch focal length camera. The runs were repeated in December 1957 and the two sets of photographs were brought back to Australia for examination.

The radial-line method was used to plot fixed control points on rock, and a number of selected common points on the glacier surface were then mapped to the same scale. Comparison of the two positions of corresponding points gave a direct measure of the displacement which had occurred between the two runs. It was found unnecessary to use more than one strip of photos for each glacier, so that only 12 to 16 photos required plotting for each set of measurements.

The period which elapsed between the two sets of surveys was 120 days, and measured displacements at the scale of the prints ranged from 0.05 to 0.68 inch, corresponding to velocities of 8.3 to 113 inches per day. Although no independent checks are available, the transverse velocity distributions given by the measurements conform to those which might be expected from established theory. Full results will be given elsewhere.

The method could easily be adapted to measure the movement of the big inland ice streams so long as rock control points and reasonably snow-free ice surfaces are present. As long time lapses are undesirable, the method as outlined is probably not suitable for use on glaciers having mid-stream surface velocities less than 15 inches per day. Flights would be best carried out at the end of one summer and again at the beginning of the next summer, so that the melt-stream patterns would undergo no change. For inland work use of the radar altimeter would be essential.

Discussion of "Needed Research in Sedimentation"

BY W. C. ACKERMANN

[*Trans.*, **38**, 925–927, 1957]

G. C. Amstutz (Department of Geology, Missouri School of Mines and Metallurgy, Rolla, Mo.)—An old Latin adage says, "Nature has made judges of all of us, but only a few artists." In this spirit it is that I would like to comment on Ackermann's interesting programmatic outline.

The present writer recently attempted to tackle one of the problems involved in desert sand sedimentation, not mentioned by Ackermann because he deals mostly with sedimentation in water, and has set up a morphogenetic function relating, tentatively, the shape $S_{x,t}$ of a sand grain at a certain place x and a certain time t to some ten factors influencing this shape. Ackermann does not mention the great amount of fine research done with regard to the role of size and shape in sedimentation.

It may be unjust to judge a man's work from a brief article. However, none of the 82 references in this and the accompanying seven papers of the Symposium on Watershed Erosion and Sediment Yields is taken from foreign literature. If this is a true picture of the work done by this Symposium I want to add a comment and a suggestion.

After the Russians sent up their sputniks we could read in most newspapers that we should not waste time in finding a better approach to many important scientific problems. As one conversant with several foreign languages, my comment is: Almost half of the average papers published in the United States are out-dated by results published previously in foreign journals, or they repeat in part what others have done equally well or better, or they are incomplete in comparison with foreign work. Often they present ideas as new which are already well known in foreign literature.

This causes us to lose time and perhaps the race. Of course it is desirable to repeat measurements for the purpose of strengthening the evidence or for other purposes. But too often a student or research worker has little idea what has been done in his field of interest in other countries. This is because of lack of knowledge of other languages. We know that the sputnik scientists were completely up-to-date on the last published advances in our country in metallurgy, physics, mathematics, and other fields important in missile research, and that many of our 'pure research publications' have helped them. Why? Because they read and use them and do not repeat our measurements and calculations if they are good.

We must decide whether we want to stick to the illusion that everything in the United States is biggest and best, or whether we will spend money for translations or time for learning a language. The fact that none of the 82 references in the eight papers of the above Symposium refer to foreign literature is alarming.

My suggestion: Much careful, extensive, and meticulous work has been done in foreign countries in the field of experimental sedimentation research and observations in nature. For lack of space I offer only one example from Switzerland's Federal Institute for Hydraulic Research. Papers by Lütschg, Meyer and others show how long ago much work was started. Probably the best international summary on sedimentation was written by Paul Niggli (Gesteine und Minerallagerstätten, Birkhäuser, Basel, vol. 2, 1949).

William C. Ackermann (Illinois State Water Division, Urbana, Ill.; Author's closure)—Amstutz has for some reason chosen to address this author whose paper was on the general subject of sedimentation and a part of the symposium noted. Although his tone is distinctly critical, some personal satisfaction is derived from the fact that little of it is directed at the author whose references in the short paper were two in number. He points to the general failure to include references to much fine foreign work which has been accomplished and reported. This is probably justified, although my paper does not attempt to summarize previous work, either foreign or domestic. It was aimed at research needed to solve problems which are developing primarily as a consequence of action programs in the United States.

Amstutz moves on rather quickly to scold the entire panel and finally all scientists in this country for the fault of not reading foreign literature. He states that more than half of the average papers published in the United States are either outdated, repeat the work of others, or are incomplete. This is a shocking situation, if true.

Whatever the proportion of originality in this country, most scientists in the United States will agree with the discusser that we in general are not sufficiently acquainted with work in other countries. Ways must be found to bring translations in both abstract and complete form to our scientific workers. This author believes this will be done.

Discussion of "Longitudinal and Transverse Diffusion in Granular Deposits"

BY G. DE JOSSELIN DE JONG

[*Trans.*, **39**, 67–74, 1958]

J. A. Cole (Department of Geodesy and Geophysics, University of Cambridge, Cambridge, England)—The writer finds the paper most valuable, because he [*Cole*, 1957] has made experiments with columns of granular material, basically similar to those described by the author, in order to determine the relative importance of: Effect (a) radial molecular diffusion in each pore combined with a velocity gradient across the pore, and Effect (b) the geometry of the pore system, in producing a longitudinal dispersion of an injected substance.

The author mentions Effect (a), but makes the assumption that it may be neglected if the pore section is small enough. Though valid, such an assumption is not often realized, as the following numerical examples illustrate. *Taylor* [1953, 1954ab] has shown that the diffusion coefficient D_S of Effect (a) with streamline flow in straight cylindrical tubes of radius a is

$$D_S = a^2 v_0^2/48\, D_m \qquad (26)$$

when

$$4L/a \gg v_0 a/D_m \gg 6.9 \qquad (27)$$

L being the distance along the tube in which the concentration of the injected substance has an appreciable gradient, and is approximately equal to 4 σ_Z. The first condition in (27) can easily be met by using large enough values of Z. Figure 6 is a presentation of D_S versus v_0 on a log-log graph, for two values of a. Where the two lines are broken the second condition in (27) does not hold, and (26) is only an approximation. In applying (26) to granular materials, which do not have cylindrical pores as a rule, one uses a mean pore radius (see $\bar{a}$ below) in computing D_S. The random orientation of the pores results in one's observing not D_S, but $D_S/\xi^2 = a^2(\langle z\rangle/\langle t\rangle)^2/48D_m$, where $\langle z\rangle/\langle t\rangle = v_0/\xi$.

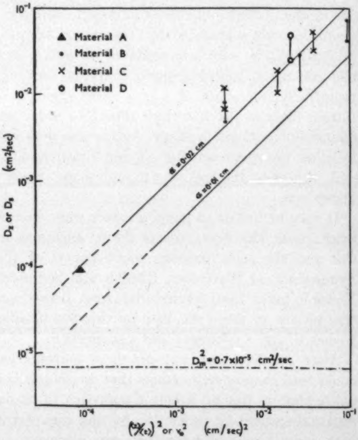

FIG. 6 – Comparison of D_s observed in the granular materials listed in Table 1 with theoretical values of D_s.

TABLE 1 – *Properties of porous columns*

Material	Composition of material	d	p	ā
		cm		cm
A	Glass beads	0.020	0.385	0.0086
B	Glass beads	0.047	0.35	0.018
C	Glass beads	0.027	0.33	0.0105
D	Clean quartz sand	0.034	≈0.33	≈0.013

Clearly a line corresponding to D_S/ξ^2, for a given value of a, plotted versus $(\langle z\rangle/\langle t\rangle)^2$ is coincident with that of D_S versus v_0 for the same value of a.

The author gives for his measurements in a glass-bead column, $\sigma_Z = 0.6$ cm when $Z = 17.0$ cm and $\langle z \rangle / \langle t \rangle = 0.55$ cm/min $= 0.0092$ cm/sec. Accordingly $D_Z = 0.6^2 \times 0.0092/34$ cm^2/sec $= 9.6 \times 10^{-5}$ cm/sec.

This value of D_Z is shown (as the point for Material A) on Figure 6. Also shown are some values of D_Z in columns of glass beads and of clean quartz sand, which were obtained by the writer. Materials A, B, C, and D have the properties specified in Table 1, where d = mean grain diameter, p = coefficient of volume of porosity, and $\bar{\bar{a}} = (d/2)[p/(1 - p)]^{\frac{1}{2}}$ = the mean radius of the pores, approximating the polyhedra to spheres.

These values of $\bar{\bar{a}}$ correspond to values of D_S/ξ^2 which are far from negligible. In Material A, the case quoted by the author, it is likely that Effect (a) was appreciable (one tenth of the observed D_Z say). In the other examples Effect (a) was of major importance, amounting to a quarter of the observed D_Z in Materials B and D, and almost all thereof in material C.

In contrast to the above laboratory experiments, the writer [*Cole*, 1957] also made field experiments with tracers flowing in chalk aquifers. These showed values of D_Z some hundred times greater than would have been expected from Effect (a) alone, and it was presumed that Effect (b) was predominant. Even that was not certain, owing to possible chemisorption effects within the aquifer.

There is thus scope for development of a fuller treatment of longitudinal dispersion in granular materials. Besides Effects (a) and (b), such a treatment would ideally include the work of *de Vault* [1943], *Thomas* [1944], and *Goldstein* [1953] on chemisorption processes in porous columns.

Further laboratory work would profit by the determination of the pore radii in the granular material, by measurement of its water content oyer a range of negative pressures [*Foster*, 1948].

G. de Josselin de Jong (Laboratorium Voor Grondmechanica, Postbox 69, Delft, The Netherlands, Author's closure)—In his discussion Cole gives further information on the deviation from our theory to be expected in experiments for which the basic assumption of piston flow in the elementary canals is unsatisfactory so that the influence of holdback can not be neglected. According to the conception of *Van Deemter* and others [1955], this holdback amounts to $H = 0.02$ in the test described, because the factor $(D_m t/a^2)^{\frac{1}{2}} = 11$, where D_m = molecular diffusion = 0.7×10^{-5} cm^2/sec, t = time to cover the distance 4 σ_z with mean velocity = 2.4 cm/0.0092 cm/sec = 270 sec, and a = radius of pores = 0.004 cm.

For the interpretation of the test results in the article this amount of holdback was considered as negligible. According to his theory Cole obtains a somewhat larger influence about one tenth of the longitudinal diffusion.

As the principal point of our considerations was to show the interrelation between longitudinal and transverse diffusion and the possibility to describe these two phenomena in one mathematical expression, the influence of holdback and molecular diffusion both were omitted in the theoretical considerations for simplicity's sake. But we do agree that these two effects and the chemisorption as mentioned in the discussion may have an overwhelming influence in certain circumstances.

In order to show the phenomenon of longitudinal and transverse diffusion we add here some photographs of a Christiansen filter (Fig. 7). This is a deposit of crushed optical glass (grain diameter 0.42 to 1.19 mm) saturated with a solution of NH_4J in water of such a concentration that both refraction indices of grains and pore liquid are equal for sodium light.

As the light is not dispersed by deviation of its direction at the interfaces of grains and liquid the system becomes perspicace. (We are indebted to the Shell Laboratory, Amsterdam, for this device.)

The pore liquid runs vertically through the

cm scale
mean velocity 0.0008 cm/sec
holdback 0.02 over 0.5cm
theoretical standard deviation
$\sqrt{\sigma_z^2+\sigma_m^2}$
$\sqrt{\sigma_r^2+\sigma_m^2}$
mean velocity 0.008 cm/sec
holdback 0.1 over 0.5cm

FIG. 7—Christiansen filter showing longitudinal and transverse diffusion

deposit. An analine dye is introduced with an injection needle. The molecular diffusion of the dye is about $D_m = 10^{-5}$ cm² sec. The photographs show the dispersion originated at two velocities, 0.0008 cm/sec and 0.008 cm/sec, which induce a holdback over a distance of 0.5 cm of respectively 0.025 and 0.10. The standard deviations originated by molecular diffusion in combination with longitudinal and transverse diffusion as computed from the theory are added in the figure for comparison.

At the lower velocity the elongation of the standard deviation ellipsoid is principally determined by the longitudinal diffusion, while at the higher velocity the influence of the holdback enters into the observation.

Discussion of "Evaporation Study at Silver Lake in the Mojave Desert, California"

BY HARRY F. BLANEY

[*Trans.*, **38**, 209–215, 1957]

N. J. Cochrane (Alliance House, Caxton Street, Westminster, London, S.W.1., England)—Blaney's paper is the latest of his invaluable contributions to large-scale evaporation studies. The fact that the shallow Silver Lake sensibly dried up during the period of observation might suggest that the data are not necessarily representative of the evaporation from a perennial lake of substantial depth in a similar situation. Nevertheless if we take the mean relative humidity H_r at say 55 pct, the mean wind speed U at ten meters as, say, seven miles per hour, the mean annual temperature T as 70°F, the writer's formula

$$e = \frac{T^2}{100} \times \sqrt[3]{\frac{U+3}{20H_r}} \times \left(\frac{60}{H_r T}\right)^{0\cdot 8}$$

suggests a value of 72 inches for the evaporation from an open lake in the circumstances.

Harry F. Blaney (Agricultural Research Service, Los Angeles, Calif.; Author's closure)—The conclusion by Cochrane, that evaporation from the shallow Silver Lake might not necessarily be representative of the evaporation from a perennial lake of substantial depth may be correct. However, these data can be used to estimate evaporation from many of the dry lakes in western United States which are occasionally filled with water during years of excessive precipitation and runoff.

No doubt the lower annual evaporation of 72 inches which Cochrane obtains from his empirical formula (using Silver Lake climatic data) is for a perennial lake. The average annual evaporation loss from Salton Sea, California, located in a somewhat similar climate to that of Silver Lake, was estimated [*Blaney*, 1955] to be 73 inches.

Cochrane [1956] should have cited the paper with the description of his formula for estimating lake evaporation. This formula was developed after a study was made of some 80 records from evaporation pans spread widely over the world. At some sites climatic data were also available. Cochrane indicates that evaporation from open water surfaces should be a direct function of temperature and wind speed and a function of relative humidity in this formula which is designed to cover a wide range of climates. Also, that his formula gives results within ±10 pct.

The author has found the formula $e = kf$ to be useful not only for computing monthly evaporation from desert lakes, but also for estimating evaporation at high altitudes during the winter months when the water in pans freezes and no measurements of evaporation can be made. [*Blaney*, 1956].

Discussion of "Problems Encountered in the Utilization of Ground-Water Reservoirs"

BY RAPHAEL G. KAZMANN

[*Trans.*, **39**, 94–99, 1958]

Harold Conkling (448 South Hill St., Los Angeles 13, Calif.; received April 14, 1958)—Kazman has made an interesting discussion of the problems encountered in utilization of ground-water reservoirs. It is just now becoming a problem which engages the attention of engineers in the humid areas of the United States but which, in some parts of the more arid regions has been recognized for at least the last 30 yr. Not only has it been a recognized problem but it is one which has been solved in some cases and will finally be solved in all.

In California it rains in winter and does not rain in the growing season. In addition, there is a long 'cyclic' variation in precipitation. Southward from the latitude of San Francisco the perennial discharge of streams becomes progressively smaller with distance. In the region generally known as Southern California, discharge of the streams in summer is almost non-existent. The region is arid. At least a century ago in this more arid portion of the State and along the coast northward, the sustained discharge had all been put to use.

A few years before the turn of the present century, wells for an irrigation supply began to be drilled in the alluvium deposited in the valleys by these same streams and charged by percolation from their winter floods. A supply, thought then to be inexhaustible, was thus tapped and the race was on. In another few years the safe yield of some of the basins was overdrawn but because of large excess capacity of the underground reservoirs, recognition of this did not come until many years afterward. The 'safe yield' means the annual yield which can be sustained throughout a period of long-time average recharge of the underground reservoir without cumulative recession of water-table. In other words it is the long-time average annual recharge.

As stated, cyclic as well as annual variation in discharge occurs. In Southern California the 'cycles' have averaged 28 years in length. Reservoir capacity five to eight times safe yield is required to iron out the variations, and generally more than that exists in the alluvium of the valley. The long cyclic rise and fall of the water table obscures the facts as to overdraft or sufficiency. Furthermore, no techniques were available for ascertaining the existence of and determining the amount of the overdraft.

About 30 yr ago, with funds appropriated by the State Legislature, techniques for ascertainment of and evaluation of overdraft were developed by State personnel but the first of such evaluations was not completed until some 15 years after the first overdraft began. In another ten years or so, Colorado River water was imported and the situation is being slowly rectified.

In the intermountain states the same problem that faced the water users of the southern half of California, began to trouble the underground water users some years later than their recognition in California. In these states not much progress has actually been made in their solution. Farther east in the Great Plains, aridity decreases and small local problems, such as described by Kazmann, exist along the streams. Over most of the area not near streams there is no problem. Underground water in commercial quantities is simply mined. Recharge is insignificant.

To this writer, the technical difficulties involved in the planned utilization of underground reservoirs do not appear great, at least in the case of those situations which he has encountered in his practice, but in many cases it is impossible to put such plans into effect until the situation has become so difficult that the majority of water users has realized that the 'inexhaustible' underground supply does not exist. No amount of persuasion is effective, nor could a consultant take time for such persuasion. Nor could he ethically pursue such a course. Events are the best persuaders.

H. W. Thoms (Edificio Monte Avila, Caracas, Venezuela; received May 23, 1958)—According to *Science*, the Population Reference Bureau has reported that "water shortages are now a national problem," and the United States "might not have enough of the precious mineral to go around" in the not-too-far-distant future. This observation is of world-wide application, and it seems only logical to develop underground reservoirs to the utmost wherever they exist. Hence, Kazmann may soon find it much easier to interest the public in projects designed to solve the problem, even though it may involve the organization of a recharge 'district.'

In Figure 2 the contours show the piezometric surface in the lower aquifer higher than in the upper aquifer, while in Figure 4 the schematic cross section shows the opposite condition. Does Figure 2 represent the original conditions in the two aquifers rather than those obtaining under the present development?

Raphael G. Kazmann (Stuttgart, Ark.; Author's closure)—Conkling's discussion, based on a wealth of ground-water experience in California, is a most welcome supplement to the original paper. The need to have reservoir storage equal from five to eight times the average annual recharge in order to maintain an offtake approximately equal to the average recharge is most significant. In a concrete fashion it puts emphasis on the phrase, "aquifiers are not subject to evaporation losses."

If reservoir capacity ample for the carry-over of water for periods up to eight years is needed, the water-costs of evaporation from surface reservoirs can be approximately evaluated. In the Southern California–Arizona area the net annual evaporation ranges from about 90 inches/yr at Phoenix to about 30 inches/yr at San Diego [*Meyer*, 1942 Appendix, pp. 39 and 46]. For purposes of illustration assume 42 inches/yr as the average net evaporation to be expected from a reservoir constructed in that region. Then the El Capitan Reservoir (surface area about 1500 ac) which is designed to carry over water from year-to-year (located on the San Diego River which has a mean annual flow of about 25,000 acft/yr) can be expected to lose approximately 5000 acft/yr, 20 pct of the average annual flow, to evaporation alone. Thus a ground-water reservoir of equal capacity could supply a firm offtake 20 pct higher than that of El Capitan. In a water-scarce area, where the value of water approximates $80 per acre foot, this advantage would be worth $400,000 a year. Even more important is the availability of the last 20 pct of the water supply, where no economically attractive alternate exists. Sea-water conversion still has as its goal the production of water at $300 per acre foot. At Lake Mead the evaporation rate is estimated at six feet per year or, for the 146,000 acres of lake surface, 876,000 ac ft/yr. Potentially replenishable ground-water reservoirs of the equal storage capacity (about 30 million acre feet) are not unusual in the southwest, but they are not burdened with that rate of loss.

Thus Conkling's words serve to emphasize, in quantitative terms, the need for fullest utilization of ground-water reservoirs. And this, in turn, implies the absolute necessity of developing an economical and effective method of ground-water recharge in the near future.

Thoms' remarks on the logic of ground-water development are fully shared by the writer: The precise timing of the necessary research will probably depend more upon the occurrence of actual water shortages than any other single factor.

Until 20 or 25 yr ago the artificial changes in river regime or weather were generally so small as to be negligible in the design of water-supply structures. More recently it has been necessary to take such changes into account in a minor way. Within the next 25 yr it may well be that plans of public and semi-public and private organizations, with regard to water control or use, will be almost as important as the long-term hydrologic observations made by the Weather Bureau, the U. S. Geological Survey and other fact-finding agencies. This paper is an attempt to call attention to this trend by citing a specific example: the regime of the Mississippi River at St. Louis.

Thom's interpretation of the illustrations contained in the original paper is correct and the writer regrets that the illustrations were not captioned more clearly.

Discussion of "Upper and Lower Frequency Curves for Peak Rates of Runoff"

by W. D. Potter

[*Trans.*, **39**, 100–105, 1958]

W. T. Wilson and *D. M. Hershfield* (U. S. Weather Bureau, Washington 25, D. C.; received May 7, 1958)—The author has noted the frequent occurrence of non-linearity in stream-flow data as usually plotted on extreme-value probability paper, and has suggested fitting these data with two straight lines, crossing at the five-year return period. This is in contrast to the usual practice of fitting a straight line, or of using a curve (which could be a straight line on some other kind of paper). It seems remarkable that the two lines should cross at five years, instead of 3.34 years or some other return period, and that they should all cross at about the same return period.

It seems remarkable also that 69 streams, having a wide variety of physiographic and climatic

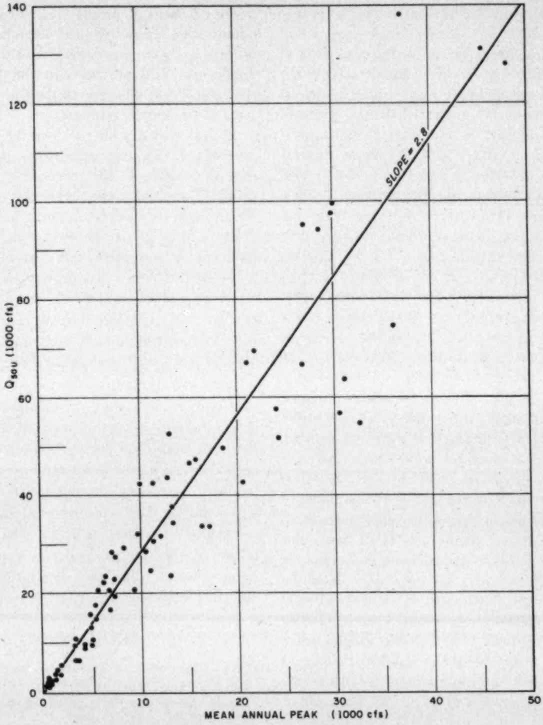

FIG. 7 – Relationship between Q_{50U} and mean annual peak

characteristics, should be found to have high correlation between the upper 50-year value and the lower 10-year value. This correlation between high and low values in the regimen of streams is necessarily associated with a fairly uniform coefficient of variation. To illustrate this uniform coefficient of variation in the author's sample it was convenient to plot his upper 50-year value against the mean value (furnished by courtesy of the U. S. Geological Survey) of the annual series for each of the 69 stations. Figure 7 shows this plot to have nearly as high correlation as the author shows for his relation of 10*L* to 50*U*, though the scatter is amplified by our having used linear paper.

The central tendency of the data in this diagram can be generalized by means of a line through the origin, and having a slope of 2.8. By multiplying the mean of the annual series by 2.8 the author's 50*U* values can be obtained more simply than by computing the 10*L* values first, and with comparable accuracy. Further, with a short record a better estimate can be made of the true mean value than of the true ten-year value.

The author has not shown that his upper 50-year values, defined by a least-squares line through the small number of points exceeding the five-year value, are superior to those obtained by any other method. We believe that the correlation between the upper 50-year and the lower ten-year values is not an adequate test of validity, but is a measure of the inherent consistency among the data in the author's sample.

Looking at this problem from a physical standpoint, a dichotomy of causes of annual peaks seems to be an over-simplification. The author has suggested several pairs of what we believe is a multiplicity of causes. This combination of many causes is one of the reasons for the statistical approach.

Manuel A. Benson (U. S. Geological Survey, Washington 25, D. C.; received May 8, 1958).—In the *Discussion* which closes his paper, the author disclaims any generality for the dog-leg shape of frequency curve or for the relations he has developed. This leaves unanswered the question of just how specific are the results which he has obtained. The sampling method and the area of applicability of the relations require explanation. The separation of a frequency curve into two distinct parts is also open to question.

It has been the experience of this writer that frequency curves of maximum annual peak discharges, when plotted on extreme-value probability paper, indicate a variety of shapes. Some are straight lines, most curve gradually either upward or downward, and relatively few appear to represent two straight lines.

The frequency curves for 96 records of annual peak discharge are shown plotted in Figure 8. These records, which have been reviewed and analyzed for publication in the series of compilation reports now being prepared for publication as U. S. Geological Survey Water-Supply Papers, represent all the long-term records available for stations with annual peaks not appreciably affected by regulation. They are generally over 45 years in length, with a median length of 53 years. They have been plotted together on a dimensionless basis by using as ordinate the ratio to the mean annual (2.33-year) flood; the shapes remain the same as though discharge were the ordinate. The curves have been drawn by eye, fitting the average trend of the plotted points as closely as possible. Most of these curves have a gradual curvature; only a very few can be interpreted as representing two straight lines. Potter's contention that the dog-leg shape "is especially noticeable when the period of record is 25 years or more" is not borne out by these curves.

Hazen [1930, pp. 102–105] speculated that the complex shape of frequency curves may be due to the multiple causes of floods. However, he concluded, "It is true of course that these causes grade into each other and that no lines of demarcation can be drawn." Potter's separation of high- and low-frequency curves at the five-year level is entirely arbitrary and does not actually separate peak discharges caused by different types of storms.

The separation of the frequency relation into two parts at the five-year level (each part made to fit a straight line) is not only arbitrary but is an oversimplification of the basic problem. Undoubtedly, this method is better than that which assumes a single straight line, yet not as accurate as one which might use say three straight lines or the curve which is the limit of n straight lines. The graphical method of fitting flood discharges is an approach towards expressing the underlying complex situation. It avoids the initial restrictions and perhaps the error of arbitrary assumptions. The range of error in the drawing of graphical curves may be smaller than that involved in assuming a fixed shape for the frequency relation.

Potter's method for finding a relation between the 10- and 50-year floods is as follows: (1) Plot the annual floods against recurrence interval on extreme-values probability paper. (2) Divide the data into two parts at the five-year point; compute a least-squares line for the upper points and fit a straight line to the lower points by eye. (3) Select values of Q_{10L}, Q_{10U}, and Q_{50} from these two lines. (4) Plot Q_{10L} versus Q_{10U} and Q_{10L} versus Q_{50} and compute least-squares lines for both. (The first line may always be expected to show good correlation, since it relates the equivalent of two adjacent points on the same frequency curve.) The second is the desired relation.

The following procedure is offered as an alternative: (1) Same as above. (2) Fit a curve to the data by eye. (3) Select Q_{10} and Q_{50} from this curve. (4) Plot Q_{10} versus Q_{50} and fit a curve by eye. This curve is the desired relation.

The writer applied this alternative procedure to Potter's data. Graphical frequency curves were used to determine Q_{10} and Q_{50} for the 69 stations in Potter's Table 1. Some of these curves (for Ohio, Iowa, Illinois, and North Carolina) were already available in published reports or in unpublished studies and were used without change. The rest were drawn independently of each other and, once drawn, remained unchanged. A plot was made of Q_{50} versus Q_{10}, as determined graphically from these curves. It was found that two-thirds of the points were included within 13 pct of the mean curve, as compared with 20 pct for the author's curve of Q_{50U} versus Q_{10L}. However, based on the discussion which follows, neither

FIG. 9 – Ratio of 50-year to 10-year flood, with subdivision into regions

this relation nor Potter's corresponding relation is considered significant.

Potter used the "sample of 69 gaged watersheds" to develop a relation of Q_{50} to Q_{10}. However, the area where this relation applies is not specified. Does it apply to the entire United States? Perhaps it applies to the Piedmont Plateau, to the West Slope of the Rocky Mountains, and to the States of Missouri, Ohio, Iowa, Illinois, and New York, because data from each of these areas have been used. If so, why are some areas represented by many stations, whereas the States of New York and Wisconsin are represented by only one station each? The writer would be interested in the method of sampling used, as the basis for selection is neither stated nor implied. When only a portion of the available data is being used, an unbiased and clearly defined sampling method is required to give meaningful results. If the developed relations apply only to selected points which happen to plot together, they have little significance.

Note that the author's curve of the relationship of Q_{50U} to Q_{10L} is a straight line on log paper at virtually a 45° angle (the slope was tested by the writer and proved not to be significantly different from 1.0). This line is equivalent to a constant ratio of 1.65 for the 50- to 10-year peak.

To investigate the variability of the Q_{50} to Q_{10} ratio for the entire United States, the writer made an independent study using the 96 long-record stations whose frequency curves are shown in Figure 8. The locations of these stations and the Q_{50}/Q_{10} ratios, determined from individual frequency curves, are shown on the map of Figure 9.

Statistical techniques are available for investigating whether a general average (of the Q_{50} to Q_{10} ratio) might be suitable for the entire United States. If the data can be grouped in some logical manner, tests can indicate whether the groups are from the same basic population. The country was divided into seven parts; the boundaries were chosen so as to separate regions of high and low ratios, as indicated by the data.

A standard analysis of variance computation was first made. The standard F test [*Snedecor*, 1946, pp. 231–233] shows the variance between regions to be very significantly larger than the variance within regions. This method assumes normal distribution of the data, an assumption which is not necessarily true of hydrologic data. A nonparametric test, the Kruskal-Wallis one-way test of analysis of variance by ranks [*Siegel*, 1956, pp. 184–199; *Wallis* and *Roberts*, 1956, pp. 599–601] was therefore made in addition. This test confirmed the result of the standard F test.

This study indicates that there are highly significant differences in the 50- to 10-year ratios which remain to be examined and, if possible, explained. The regions as outlined in Figure 9 are not necessarily the best way of subdividing the country. The picture will no doubt be changed as more long-term records become available. The means and medians of the separate groups indicate that possibly some of the seven groups might be combined. However, the groups which represent the extremes should not be considered together; for example, groups 2 and 5, having low ratios, and groups 3, 6, and 7, having high ratios, should not be considered as part of the same population.

The author's method has been proposed as a means of using short-term records to predict 50-year floods. Well-established methods are available for using short-term records together with long-term records in developing regional flood-frequency relations. These regional methods reduce the chance error inherent in individual records, particularly short records, and furnish estimates of not only the 50-year flood but of floods of any recurrence interval within the time range of the longer records, at either gaged or ungaged points.

R. Robinson Rowe (California Division of Highways, Sacramento, Calif.; received June 17, 1958) —All techniques refining observations of extreme floods on a frequency basis add to our knowledge, by induction, of the real laws of nature. The addition may be in the form of new hypotheses or support for the old. Potter's paper contains both elements.

His end result appears to be the two unnumbered equations on page 101, the difference of which is

$$\log Q_{50U} - \log Q_{10U} = 0.166 + 0.001 \log Q_{10L}$$

Since the last term never exceeds 0.002 for his data, it may be ignored to find

$$Q_{50U} = AQ_{10U} \quad \text{where} \quad A = e^{0.166} = 1.47$$

TABLE 2 – *Group summary of basic data*

Group	Items	Values of A		
		Min.	Mean	Max.
Iowa	9	1.30	1.62	1.88
Piedmont	21	1.21	1.54	1.86
Missouri	12	1.26	1.51	1.77
Western	8	1.26	1.47	1.71
Ohio	10	1.22	1.39	1.67
Illinois	7	1.17	1.38	1.65
Miscellaneous	2	...	...	...
Total	69	1.17	1.50	1.88

If we now examine the ratio A of Q_{50U} to Q_{10U} for the 69 streams of his Table 1, by groups, we find (Table 2) strong indications of heterogeneity. The groups have been rearranged in order of mean value of A, which ranges from 1.62 in Iowa to 1.38 in Illinois. With one exception, the maximum and minimum values of A follow the same order, indicating similar dispersion of the basic data.

If the several groups are all part of a homogeneous region the conformance would be accidental and A would be constant near 1.50 (the mean) or 1.47 (as derived above). The dispersion (1.17 to 1.88) would be a measure of error due to short records, expressed by quartiles as 1.50 ± 0.16.

On the other hand, if the conformance is systematic, the region may be a heterogeneous collection of relatively homogeneous sub-regions for which A ranges from 1.38 to 1.62 but is nearly uniform in each group. For the largest group, the quartile measure of error would be expressed as 1.54 ± 0.13. The writer prefers this interpretation even though the adjoining regions of Iowa and Illinois differ the most.

The ratio A for two California regions can be scaled from another study of this problem [*Rowe* and others, 1957], finding $A = 1.58$ in northwestern California (Fig. 4) and $A = 1.98$ in the Sierra Nevada Mountains (Fig. 5). Station records would have ranged from 1.2 to 2.8. Hence the two studies agree in principle that the ratio A is an important hydrologic factor for a watershed which is constant (within a moderate range) for a homogeneous region, and that this constant is approximately determinable by combination of poorly-defined short-period station records.

Both studies also call attention to and dispose of the characteristic dog-leg form of frequency curves. Agreeing that the shape is caused by sampling from two different populations, the author presumes enough correlation between the populations to define empirical relations. The writer prefers the referenced California study which discards the minor population, apparently distinguished by its plotting along the lower limb of the dog leg.

To support the diagnosis that dog-leg frequency curves derive from mixed samples, the author presented Fig. 6 to show a clean sample from a melt stream with a fairly straight curve. Although he described it as having "no dog leg at all," a better fit can be obtained with a slight dog leg. Replotting to include the 1956 flood (1680 cfs), the dog leg is substantiated with the following values

$$Q_{2L} = 0.74, \quad Q_{10L} = 1.09, \quad Q_{10U} = 1.16,$$

$$Q_{50U} = 2.05 \quad A = 1.77.$$

So, while this stream (Bear Creek near Lake Thomas A. Edison) is usually a melt stream, its record of peaks is a mixed sample. All but the two largest were melt floods in May and June. The other two were due to heavy rain on a snow cover, July 21, 1936, and July 26, 1956.

ROWE, R. ROBINSON, GORDON L. LONG, AND THOMAS C. ROYCE, Flood frequency by regional synthesis, *Trans. Amer. Geophys. Union*, **38**, 879–884, 1957.

W. D. Potter (Bureau of Public Roads, Washington, D. C.; Author's closure)—I wish to thank the discussers for their interesting comments. Since writing the paper, I have had the occasion to establish the relations between Q_{10L} and Q_{50U} for three physiographic areas; namely, (1) the Adirondack, White Mountains, and Maine Woods area, (2) the New England Hill and Lowland area, and (3) the Southern Rocky Mountains area. It was found that, by establishing these relations for individual physiographic areas, the spread of the error bands for 68 pct of sample was reduced from one-half to one-fourth of the ±20 pct found for the sample used in the paper. The relations between Q_{10L} and Q_{10U} and between Q_{10L} and Q_{50U} were used in analyzing peak rates of runoff for each of the above physiographic areas.

Reviews, Abstracts, and Bibliography

Reviews and Abstracts

GEORG WÜST, *Wissenschaftliche Ergebnisse der Deutschen Atlantischen Expedition auf dem Forschungs- und Vermessungsschiff-Meteor, 1925–1927*, vol 6, part 2 section 6, Stromgeschwindigkeiten und Strommengen in den Tiefen des Atlantischen Ozeans, pp. 261–420, Walter de Gruyter and Co., Berlin, 1957.

It is with a feeling of reverence that I take up the task of reviewing Dr. Georg Wüst's most recent contribution to the long and distinguished series of volumes of reports of the German *Meteor* Expedition (to the South Atlantic Ocean) of 1925–1927. For over thirty years now the reports of the *Meteor* Expedition have set the highest standard for publication of the results of oceanographic investigation: complete documentation of the actual original data obtained, the methods of observation, definitive and handsome atlases and complete and explanative studies and interpretation of the meaning of the results. Since the time of the *Meteor* Expedition, much oceanographic survey work has been done, but never in quite the same systematic way, nor have the results of any of the later expeditions been written up in such a thorough fashion: indeed the *Meteor* work has been the model after which the recent IGY surveys of the Atlantic have been made. Wüst has long been recognized as the world's leading authority on the deep circulation of the ocean, not only in the South Atlantic, but in the oceans of all the world. There is no one who has immersed himself more deeply in the study of hydrographic observations, and no one else has contributed so much toward developing a comprehensive picture of the circulation of the world ocean as a whole. Because this is Wüst's last contribution to the *Meteor* reports, and in view of his imminent retirement as Director of the *Institut für Meereskunde der Universität Kiel*, it is appropriate to express here, in this review, the admiration and gratitude of the world's oceanographic fraternity for the legacy and fruits of his wisdom and industry. And we can hope that in his retirement he will be able to favor us, from time to time, with the products of his deep understanding of the ocean.

In the first three chapters Wüst presents a complete compilation in tables, graphs, and profiles of the vertical distribution of specific volume and dynamic depths for all the *Meteor* data. Using the level of no motion proposed by *Defant* [1941], Wüst proceeds, in Chapter 4, to present complete profiles with contour of constant geostrophic velocity. In Chapter 5 the amount of mass transport between each pair of stations and between standard depths is also presented. Finally, in Chapter 6, computations of the transport of salt and of dissolved oxygen are presented. All these computations are reproduced in complete detail so that the reader can have no difficulty reconstructing all portions of the argument.

During recent years [*Iselin*, 1955] there has been growing concern over the accuracy and limitations of geostrophically computed currents. Occasionally, in councils of despair, it has been suggested that the method is hopelessly inaccurate and that the mean circulation is dominated by gross turbulent viscosity. Wüst has made use of an intuitively chosen reference level (of no motion) originally proposed by *Defant* [1941] on purely intuitive grounds (a possible physical basis is given by *Stommel* [1958, p. 158]). The results of the computation for transport through the *Meteor* profiles are summarized in Tables 12 and 13; pages 368 and 370 are quite remarkable for the high degree to which a balance between flows northward and southward is achieved. Does this mean that the geostrophic method is vindicated as good beyond all expectations?

First, of course, it is no surprise that the Defant reference level should be a first approximation of the truth: it would probably not have been used by Wüst if it had not already passed a preliminary test by Defant with the *Meteor* data.

Second, the very large transports ΣW that appear in Table 12 are largely made up of rather small scale pairs of nearly balancing currents and countercurrents occurring between successive stations (these can be seen in extreme form in the isotach profile II on page 330). As Wüst explains (p. 369), were a profile to contain more stations, one would expect more current-countercurrent, and hence the individual ΣW_+ and ΣW_- values to increase, but the balance to remain unaffected. Wüst does not claim that these pairs of currents in mid-ocean (above and below the arbitrary reference level) are all permanent oceanic features; the fact that such a careful author does not lay more stress upon them suggests that he prefers not to interpret them as bona fide current systems, but leaves the possibility open that some may actually be due to momentary disturbances of the density field of a short duration. Such ambiguities are part of the reason why other oceanographers have been so uncomfortable about the geostrophic approximation. When transports per unit depth are computed for the full width of an ocean basin, or for the whole western or eastern trough, the contribution of these ambiguities is minimized, as Wüst shows, and one is bound to agree with the author that these integrated transports compare most beautifully with the expectations of water mass analysis (the intermediate water excepted) each computed current maximum coinciding nicely with the center of a particular water type.

A good balance is also obtained for salt-transport (integration over a whole profile of the product of mass transport and salinity) but as Wüst points out this result is really quite insensitive to the actual salinity distribution in the profile. In fact, he shows that much the same result can be obtained by multiplying the net mass transport for the profile by the mean salinity. Thus the salt-transport computation does not serve as an independent check on the consistency of the Defant reference level and geostrophic approximation. This shows that an attempt to work backwards from the principle of conservation of mass and salt, and thus to determine the reference level, is in fact impossible (although it seems to work for small straits and estuaries [*Sverdrup* and others, 1942, p. 426, 457]).

One of the main results of Wüst's study is the amazing concentration of deep currents in limited, narrow, high velocity western boundary currents often lying right on the continental slope of South America. The existence of these currents has an important bearing on theoretical studies of the deep circulation [*Stommel*, 1958, pp. 157–172]. Profile VI (p. 333) shows them in beautifully developed form although they are not so clear on other profiles for example, Profile II, p. 330). So narrow that they often fall between two stations, with computed velocities of as much as 17 cm/sec, they carry a large fraction of the total meridional transport of water, the remaining immense water masses to the east being relatively slow moving. Were a particle able to remain inside so swift a stream, and were the stream itself a continuous ribbon, only a few years would suffice to carry it from the South Atlantic. This rapid motion should not be confused with the turn-over time (residence time or age) of deep water because most of the deep water does not move so swiftly, and is presumably in active exchange by lateral mixing processes with these western boundary currents. This reviewer thinks that our hypothetical particle could not stay in a western boundary current for long, but would quickly be transported out into the slower moving immense water masses in the middle of the ocean; that much of the turbulent exchange from the western boundary current is by lateral mixing with the interior, rather than by vertical mixing; and that therefore Wüst's tabulation of vertical Austausch only (p. 343, Table 3, Col. 11) is somewhat misleading and that the real values are much lower. My reason for feeling that there must be a relatively large lateral exchange of salinity, temperature, and dissolved oxygen between the western boundary current and the interior is that their water-mass properties are so similar despite the fact that their velocities and transports are so different. In the absence of any marked interchange one might expect a very marked contrast in water-mass properties, particularly oxygen, between them. Indeed it was this very lack of contrast which earlier led oceanographers to think of the deep circulation as a broad sluggish meridional transport fairly uniformly distributed over the entire width of an ocean basin.

Other reasons for supposing that the western boundary currents are not perfectly defined steady ribbons of flow are that from profile to successive profile there is a marked variability in the strength of the current (for example, see Table 28, p. 347), and that the profiles of the *Crawford* (1957) along 8°S and 16°S, seem to show details in the western boundary current region that are different from those in the corresponding *Meteor* profiles (VIII and VI). Over most of the deep water, however, according to Fuglister, the recent *Crawford* sections show virtually no difference from those of the *Meteor* some 30 years ago, thus verifying, in a most convincing manner, the assumption by Wüst that the deep circulation is in a climatologically mean steady state.

In retrospect it seems that Wüst, by means of this latest addition to the *Meteor* series, has been able to bring his whole concept of the circulation of the Atlantic into sharper focus, and that there can hardly be any doubt that he has been able to delineate the main features of this great natural phenomenon. By providing us with the rich detail of the complete dynamical calculations of the *Meteor* data he has given us a ready source of material for thinking about the strengths and weaknesses of the geostrophic approximation. And by his personal example of rigorous and meticulous adherence to the data itself and his thorough study of it, without frills, and with a minimum of speculation, Wüst will influence many oceanographers in the years to come. Let us applaud him.

This book is a printed record of the Proceedings of the First Conference on the Physics of Clouds and Precipitation Particles which convened at Woods Hole, Massachusetts, September 7–10, 1955. Organized under the impetus of the Committee on Cloud Physics of the American Geophysical Union, the meeting was sponsored by the Geophysics Research Directorate of the Air Force Cambridge Research Center and the Geophysics Branch of the Office of Naval Research with the cooperative assistance of the Woods Hole Oceanographic Institution.

This book is a useful reference volume for anyone interested in the study of the physics of natural clouds and precipitation. It is divided into several parts according to subject matter as follows: (1) Aerosols; their origin, distribution, and measurement; (2) Condensation and coagulation; measurement of cloud- and rain-drop size, rain from water clouds; (3) Melting and freezing; studies of snow and ice in the generation of precipitation; and (4) Crystal growth and nucleation; laboratory and field studies. In addition there are two papers, one on thunderstorm electricity and another on 'International Terminology,' which are not included in the previous four classifications.

The initial value of the conference in gathering together the leaders in research in these fields for discussions is considerably augmented by the publication of this permanent reference volume. However, the conference was not called to discuss "The Artificial Stimulation of Rain" and indeed such a title would have been considered unfortunate at the time when New England was still staggering from the floods which had occurred only three weeks previously. Unfortunately, in the final rush to get the book into print, the editors did not have an opportunity to approve the final title selection.

However, for those who buy the book on the basis of its title there are to be found therein (1) the results of using common salt for cloud-seeding experiments in Pakistan, and (2) a study of the overseeding of cumulus clouds. Needless to say, however, the basic research discussed is a necessary forerunner to the complete understanding of physical cloud processes which may lead to successful future control of such processes by man. Among the many interesting topics are some discussions of Bowen's controversial hypothesis on the meteoritic origin of world-wide rainfall singularities by Christian E. Junge and Vincent J. Schaeffer plus the results of an experiment to test Bowen's hypothesis by means of daily freezing nuclei counts. The latter paper is by A. Richard Kassander, Lee L. Sims, and James E. McDonald.

The reader will also be pleased to note the various techniques which have been used by the authors to explore clouds from within by various sampling processes and by radar.

Each paper is followed by an apparently verbatim account of the lively discussions which took place. A pleasing note is the inclusion of a frontispiece consisting of a photograph of the conference participants.

Notes and Personalia

Notes

Corrigendum—In the paper by S. Irmay in the August 1958, issue of the *Transactions*, page 705, the last line, Eq. (34) should read

$$J/[(a/2) + \sqrt{(a^2/4) + Jb}] = Jf(J)$$

instead of as shown, the radical having been omitted in the left-hand member.

National Science Foundation Graduate and Postdoctoral Fellowships for 1959–1960—The National Academy of Sciences - National Research Council will again assist the National Science Foundation in its eighth regular predoctoral and postdoctoral fellowship programs. There is the plan to award about 1000 graduate and 200 postdoctoral fellowships under these programs for the next academic year. Fellowships are open to all citizens of the United States and are awarded solely on the basis of ability in mathematical, physical, medical, biological, and engineering sciences. The closing date for the postdoctoral fellowships is December 22, 1958, and for the predoctoral fellowships, January 5, 1959. Inquiries should be addressed to the Fellowship Office, National Academy of Sciences - National Research Council, 2101 Constitution Avenue, N. W., Washington 25, D. C.

Structural Research Program in Seismology—California Institute of Technology has announced the installation of 100 small, inexpensive seismographs in Los Angeles and San Francisco in an effort to determine the characteristics by which soils absorb earthquake shocks and which soils are better than others. This is of especial concern in building and bridge construction. The study is under the direction of George W. Housner, Professor of Civil Engineering and Applied Mechanics at the Institute.

New Examination for Geodesists—The Civil Service Commission has recently announced (Announcement No. 168 B) an examination with no closing date for geodesists at salaries ranging from $4,040 to $12,770 per year in grades ranging from GS-5 to GS-15. For details get in touch with one of the offices of the U. S. Civil Service Commission.

Grant for High Energy Nuclear Particle Research in Balloons—The National Science Foundation has made a grant of $450,000 to the University of Chicago for work with a group of scientists under Marcel Schein for the study of tiny nuclear explosions with energies on the order of ten thousand billion electron volts by means of balloon flights to altitudes of 120,000 ft.

New Publication in Meteorology—A new publication entitled Nubila is now being published quarterly by the Unione Nazionale Antigrandine, Via Pellicciai, 17, Verona, Italy. The Editorial Committee consists of G. Fea, F. H. Ludlam, E. Rosini, P. M. Saunders, and O. Vittori, with Ovidio Romanelli as Director. The first number is devoted to the hail problem, a paper by F. H. Ludlam.

New Publication in Geology—The Universidad Industrial de Santander has released Number 1 of its *Boletín de Geología*. The first number contains two papers, one entitled "La Morfoestructura de la Zona de Mesas al SW de Bucaramanga," by M. Julivert, and the other entitled "Observaciones sobre la variabilidad de las especies," by J. de Porta. Interested persons should address the Fondo Rotatorio de la Universidad Industrial de Santander, Apartado Nacional 162, Aéreo 678, Bucaramanga, Colombia, S. A.

Geothermal Power Plant Opened in New Zealand—New Zealand has recently started operation of its first geothermal steam power plant at Wairakei, 60 miles south of Rotorua on the North Island, with a capacity of about 250,000 kilowatts. Explorations are being made for further development in other nearby areas which may be even more favorable for the production of power.

New Edition of the *American Practical Navigator*—This book, commonly known as "Bowditch," after Nathaniel Bowditch, author of the first edition, has been completely revised by the U. S. Navy Hydrographic Office. The new 1524-page edition became available December 6, 1958, from the Superintendent of Documents, Washington 25, D. C., at a price of $6.25.

Bathyscaphe Acquired by the U. S. Navy—The bathyscaphe *Trieste*, launched by Auguste and Jacques Piccard in 1953, and which was rented for research dives off Capri in the Mediterranean, was recently purchased by the U. S. Navy.

New Volcano in Ruanda-Urundi—Word has come that early in August a new volcano developed in the extensive equatorial rain forest in the eastern part of the Belgian Congo about 35 miles north of Lake Kivu. The cone was estimated to be about 400 ft high and a quarter of a mile in diameter early in September, with lava flows as long as 15 miles. It has been named Kitsimbanyi, which means 'high and strong.'

Russian Studies of Glacier Thickness and Structure—The Zailiyskiy Glacier Expedition of the Academy of Sciences, USSR, is making a study of the thickness and structure of the Tuykus Glacier using electrical and magnetic methods which are indicated to be much less cumbersome and expensive for such purposes than the seismic method.

Second Caribbean Geological Conference—This Conference is to be held at the University of Puerto Rico, Mayaguez, Puerto Rico, January 5–9, 1959, by arrangements with the University of Puerto Rico in cooperation with the Economic Development Administration of the Commonwealth of Puerto Rico. Sessions will be held on general problems of Antillean structure, geology of various parts of the Caribbean, economic geology, and other subjects and will be joined with several field trips. Accommodations, however, are quite limited. Communications regarding this should be addressed to John D. Weaver, who is Chairman of the Committee on Arrangements, Section of Geology, College of Agriculture and Mechanic Arts, University of Puerto Rico, Mayaguez, Puerto Rico.

Course on the Biology of Stream Sanitation in Munich—Word has come from the Bayerische Biologische Versuchsanstalt of an introductory course on the Biology of Sewage and Stream Sanitation to be held March 2-6, 1959, under the direction of R. Demoll and H. Liebmann of the Research Institute. This will be followed October 5-10, 1959, by an advanced course on "Possibilities and Limits in Removing Poison and Radioactive Substances from Sewage and Industrial Waste Waters." The registration fee for each of the courses is DM 60, including traveling expenses on excursions. Interested persons should get into touch with Prof. Dr. H. Liebmann, Bayerische Biologische Versuchsanstalt, Veterinärstrasse 13, Munich 22, Germany.

Meeting on Agricultural Meteorology of WMO—The Commission for Agricultural Meteorology of the World Meteorological Organization held a three-week meeting in Warsaw, Poland, closing on October 17, 1958. Representatives from 32 countries were present. The meeting dealt with the various aspects of meteorology of interest for agriculture and forestry, including weather forecasting for forest-fire prevention and frost warnings. The session was presided over by J. Burgos of Argentina, and near the end of its meeting elected Austin Bourke (Assistant Director for Research and Development, Meteorological Service, Dublin, Ireland) as President and M. S. Kulik (scientist of the Central Forecasting Institute of the Hydrometeorological Service of the USSR) as Vice President. Attending from the United States were William E. Hiatt and Milton L. Blanc.

Conference on the Arid Zone—Arid Zone Research has become a major project of UNESCO and held its fourteenth session at Teheran, October 7-9 and 19, 1958. Reports of the activities since the last meeting in 1957 were presented. Details may be secured by writing to the UNESCO office in Paris. Attending from the United States was C. W. Thornthwaite.

Personalia

S. Joshua Buckwold has resigned his duties as Assistant Professor of Chemistry at New Mexico Institute of Mining and Technology to accept an Associate Professorship at the College of St. Joseph in Albuquerque, New Mexico.

Bernard Haurwitz, Chairman of the Department of Meteorology and Oceanography of New York University, has accepted a position as Professor of Astrogeophysics at the University of Colorado and a member of the staff of the High Altitude Observatory. He will take up his new duties in June 1959.

Weikko A. Heiskanen, Director of the Geodetic Institute of Helsinki, Finland, and of the Institute of Geodesy, Photogrammetry and Cartography of Ohio State University, has recently been awarded an honorary degree of Doctor of Technology by the Finland Institute of Technology on the occasion of the Fiftieth Anniversary of the Institute.

Koji Hidaka, Professor at the Geophysical Institute of Tokyo University, has been elected a member of the Pacific Science Council to take the place of A. P. Elkin of Australia.

W. T. Holser has left his work at the Institute of Geophysics, University of California, to take up a research position in the Geology Division of the California Research Corporation at La Habra Laboratory.

Benjamin G. Holzman, Colonel in the U. S. Air Force, has been made Commander of the Air Force Office of Scientific Research with headquarters in Washington, D. C.

Arno T. Lenz has been appointed Head of the Department of Civil Engineering at the University of Wisconsin. He has been a member of the University staff since 1929.

Gösta H. Liljequist has been designated as Director of the Department of Experimental and Theoretical Meteorology of the Meteorological Institution at the Royal University of Uppsala, Sweden.

Morton J. Rubin, U. S. Weather Bureau meteorologist stationed with the Soviet IGY Antarctic Expedition at Mirny, reports a new world's record low temperature observed at Sovetskaya (78°24'S., 87°35'E.) on June 25, 1958, when the temperature fell to −117.4°F or −83.0°C. Details of this observation are published in the Monthly Weather Review for June 1958. A later report published in Moscow in vodnyy Transport for August 19, 1958 states that V. Babarykin, chief of the Sovetskaya station, registered a temperature of −86.7°C on August 9, 1958.

R. D. Russell, formerly an Assistant Professor at the University of Toronto, has been appointed Associate Professor of Geophysics at the University of British Columbia.

Arthur H. Waynick, Professor and Head of the Department of Electrical Engineering and Director of the Ionosphere Research Laboratory at Pennsylvania State University, has been appointed Program Director for Engineering Sciences of the National Science Foundation.

Wesley Winans Horner, Consulting Engineer of St. Louis, died September 22, 1958, at the age of 75. He was born at Columbia, Missouri, and took his baccalaureate degree from Washington University in 1905. This school awarded him a professional degree in 1909 and an honorary degree of Doctor of Engineering in 1952. His early career was devoted to engineering in the service of the city of St. Louis, becoming Chief Engineer in 1932. He opened a consulting practice in 1916, to which he devoted full time from 1932 onward, organizing the firm of Horner and Shifrin in 1933. During this interval he served his alma mater as Lecturer and Professor of Sanitary Engineering from 1934 to 1942, and served the Federal government as a consultant in various ways. He had been a member of the AGU since 1938.

Pierre Lejay, well-known Jesuit scientist, died October 11 at the age of 61, on shipboard en route to his home in Paris following his attendance at the General Assembly of the International Council of Scientific Unions in Washington, D. C. He was Vice President of ICSU, had been active in the International Union of Geodesy and Geophysics for many years, and was currently Chairman of the French National Committee for the IGY.

Union, Section, and Committee Activities

Minutes of Executive Committee Meeting, American Geophysical Union, October 18, 1958

The meeting was called to order at 09h 00m in the Tayloe-Cameron Rooms of the Cosmos Club, 2121 Massachusetts Ave., N.W., Washington, D. C., by Vice President Lloyd V. Berkner, who reported that President Maurice Ewing had been delayed and that routine matters would be taken up until he arrived.

Present—P. H. Abelson, L. H. Adams, L. T. Aldrich, L. R. Alldredge, W. W. Atwood, Jr., Lloyd V. Berkner, Walter H. Bucher, J. J. Capello, Maurice Ewing, Robert E. Gebhardt, W. C. Hendrix, Harry H. Hess, Albert J Hoskinson, Floyd W. Hough, B. F. Howell, Jr., Patrick M. Hurley, Woodrow C. Jacobs, J. W. Joyce, H. E. Landsberg, Walter B. Langbein, L. M. Murphy, J. H. Nelson, James A. Peoples, Jr., Charles Pierce, D. W. Pritchard, John C. Reed, A. Nelson Sayre, J. Frank Schairer, Waldo E. Smith, Charles A. Whitten, and Ralph N. Wilson.

Approval of minutes—The minutes of the Executive Committee meeting held on May 4 and 7, 1958, and published in the August 1958 issue of the *Transactions* (pp. 755-766), were approved.

General Secretary's Report

The last report of the General Secretary is recorded in the minutes of the Executive Committee meeting of May 4 and 7, 1958, published in the August 1958 issue of the *Transactions* (pp. 755-758). Since that time the following changes in our Executive Committee have taken place: H. Burr Steinbach of the University of Chicago has succeeded L. A. Maynard as Chairman of the Division of Biology and Agriculture of the NAS-NRC, Ernest H. Volwiler of Abbott Laboratories has succeeded Frederick D. Rossini as Chairman of the Division of Chemistry and Chemical Technology of the NAS-NRC, and John N. Adkins has succeeded Harry H. Hess as Chairman of the Division of Earth Sciences of the NAS-NRC.

Actions of Executive Committee by mail ballot—Since the last meeting of the Executive Committee there have been 13 actions by the Committee by mail ballot as follows:

Date	Subject	Approve	Disapprove
1958			
May 20	Corporation Members: W. F. Sprengnether Instrument Co., Radio Corporation of America, International Business Machines	41	0
June 2	Corporation Members: General Dynamics Corp., Bell Telephone Laboratories, Union Carbide Corp., Stanford Research Institute	41	0
June 27	Fourth list of new members	40	0
June 30	Corporation Member: Geophysical Associates International	40	0
July 2	Provisional Budget for fiscal year 1959	33	2
July 3	Corporation Member: International Telephone and Telegraph Corp.	38	0
July 9	Changes of rules for elections	37	0
July 9	Corporation Member: Standard Oil Co. of New Jersey	37	0
July 16	Corporation Member: Ramo-Wooldridge Corp.	37	0
Aug. 12	Approval of co-editors for *JGR*	36	2
Aug. 19	Fifth list of new members	39	0
Sep. 19	Sixth list of new members	38	0
Sep. 24	Corporation Member: Motorola, Inc.	38	0

In addition, one more ballot is pending at this time relating to the seventh list of new members for 1958.

It should also be reported that the ballot to the membership on the changes in the Statutes was overwhelmingly in favor of the change by about 28 to 1 according to the Tellers' report which will be presented later. Over 2200 votes were cast. Although we are still awaiting word of a grant from the National Science Foundation to aid us to expand the content of our new scientific journal, the officers have been proceeding on faith that this matter will be taken care of in due course, and plans are developing rapidly to issue the new journal promptly in January 1959.

Publications—The following issues of the *Transactions* have been printed and distributed since our last meeting:

June 1958	230 numbered pages of text plus 18 unnumbered pages including 8½ pages of paid advertising; edition of 6400
August 1958	192 numbered pages of text plus 16 unnumbered pages including 9 pages of paid advertising; edition of 6400

The October 1958 issue is in the final stages of publication in the hands of the printer, and will contain 220 numbered pages of text plus 20 unnumbered pages including 9 pages of paid advertising, with an edition of 6400. Immediately inside the front cover of the October issue we plan to publish a four-page promotional leaflet relating to the publication policy. The first page of this will be the front cover of the new journal, and the second page will be essentially the inside front cover insofar as it can be prepared at this time. The third page will be devoted to an outline of the endeavor both with regard to the new monthly journal and the new quarterly *Transactions*, while the fourth page will contain a list of forthcoming papers in the new monthly journal.

We have continued to publish the *IGY Bulletin* in each issue of the *Transactions*. Aside from the *Bulletin*, the number of printed pages has been somewhat larger than we had anticipated because we want to reduce the backlog of papers on hand to a minimum so that the editors of the new journal would have a free hand to develop the journal in accordance with proposed plans. This increase in the number of regular text pages, plus the increase in printing costs, is causing a substantial deficit. An application for a grant of $15,000 to cover this deficit has been submitted to the National Science Foundation. No formal word has as yet been forthcoming, but informal word is that late in October we will receive a grant covering this.

Advertising in the *Transactions* has continued about nine pages an issue. Our advertising representative is faced with a difficult task in selling more advertising at this time because the format and content of the new journal are still in the planning stages. There is some thought also that even though we believe that the chief advertising medium should be our new journal, we might also carry advertising (if advertisers so desire) in the new quarterly *Transactions*, perhaps offering a combined rate to those who advertise in both. The basic rate for advertising in the new journal will be $250 per page, offering a 6-number contract for the price of five and a 12-number or one-year contract for the price of nine. The same basic rate will apply to the quarterly *Transactions*, namely, $250 per page, with a 4-number contract at the price of three. A combined contract for both the *JGR* and the *Transactions* would be 16 numbers for the price of 11. This would apply only to advertisers taking a full year's advertising in both publications.

The Editorial and Publication Committee has met regularly at bimonthly intervals to consider the many problems of the *Transactions*, as well as to cooperate in the development of plans for the new journal. It plans to have its last meeting on November 20. All of the current editors have been invited to serve as associate editors on the new journal. A total list of about 30 associate editors, including foreign associates, is being established, one-third of whom will retire at the end of each year.

With regard to plans for the new journal, the Executive Committee has approved by mail ballot the appointment of Philip H. Abelson and James A. Peoples, Jr., who will serve as co-editors in chief, with the editorial office of the Union for the journal being established with Peoples, ℅ Department of Geology, University of Kansas, Lawrence, Kansas. Mrs. Peoples is being designated as an editorial assistant to take care of the mechanics of editing and to handle a great deal of the detail relating to the publication of the journal. It is anticipated, however, that the proofreading of the journal will be undertaken in the office of AGU.

Geophysical Monograph No. 2 entitled *Geophysics and the IGY* was published in July 1958 about five weeks after the receipt of the last copy from authors. Twelve hundred and thirty copies have been sold to date, and, after supplying certain review copies (24) and one to each author (34), we now have on hand 1043 copies for sale. The total edition was 2331. We still have on hand 405 copies of Geophysical Monograph No. 1.

An application for a grant of $3800 has been made to the National Science Foundation to enable us to proceed with Geophysical Monograph No. 3, which would contain papers presented at the Conference on Atmospheric Chemistry of the Compounds of Chlorine and Sulphur held in Cincinnati, November 4–6, 1957, under the joint sponsorship of the Public Health Service and the AGU with the support of a grant from the National Science Foundation. This application has been pending since March 20, 1958, and we have informal word that it has been approved.

We plan to file an application for a grant for the underwriting of a number of monographs, say, three to five a year, over the next several years. The National Science Foundation has requested that a Monograph Board be established prior to the filing of this application and that information on contemplated numbers of this series be supplied in the grant application. These matters are pending.

The Russian translation project is still moving slowly. Pergamon Press has now delivered the first five numbers of *Izvestiia* (Geophysics Series) for 1957, and a single copy of No. 7 arrived October 14 of which no quality evaluation has yet been made, leaving six still to be published. The quality of the translations is somewhat improved from the earlier two numbers. Nos. 6 and 8 are reported to be nearly finished. Members of the Board and others have reviewed the typescripts of the translations for Nos. 9 to 12, inclusive. This will doubtless improve the quality of the translations substantially. A supplementary grant to provide for the completion of this is momentarily expected from the National Science Foundation. We have applied to the National Science Foundation for continuation of the translation of *Izvestiia* for 1958, and we understand that the funds will be forthcoming within the next few weeks. The method of procedure has not yet been settled. However, the proposal to carry on the project by translators selected by AGU has received considerable support. This would involve establishment of a system similar to the one used by the American Institute of Physics for the *Journal of Experimental and Theoretical Physics* with a translation editor, a panel of translators, and arrangements with a lithographic concern to set up (we might undertake the composition ourselves in the way that we formerly handled the *Transactions*), print, and distribute the English edition of the journal. We also have applied to the National Science Foundation for a grant to translate and publish an English edition of *Trudy* of the Geophysical Institute of the USSR for 1958.

The project for the translation of abstracts has been formally terminated, and the balance on the grant has been returned to the National Science Foundation.

Membership—Membership data as of October 6, 1958, are:

Membership as of April 21, 1958	5008	
(This figure included 148 tentatively dropped, of whom 20 have been reactivated and 10 transferred to resigned)	20	
Reactivated	1	
New members, April 21 to October 6, 1958	132	5161
Resigned	47	
Inactive	1	
Dropped	8	
Deceased (reported since April 21, 1958)	6	62
Total October 6, 1958		5099

Dues unpaid—As of October 1, 1958, the following dues were unpaid:

Owe for 1958	232
Owe for part of 1958	6
Owe for 1957 and 1958	147
Owe for part of 1957 and all of 1958	6

It was reported on May 4 that 148 persons had not paid dues in full for 1956 and for the years subsequent thereto. In accordance with the instructions of the Executive Committee, these people were urged to continue their membership in AGU; 20 have paid their dues in full and are again members in good standing, ten paid for 1956 with a request that their names be entered as resigned, and 118 have been dropped. It would thus appear that our effort to restore as many of these people to good standing as possible was not by any means fruitless.

Deaths—The following six deaths have been reported to the office of AGU since our last meeting: Robert L. Pendleton, June 23, 1957; Albert C. Hornady, July 5, 1957; Harry O. Wood, February 4, 1958; Victor H. Jones, March 6, 1958; Townsend Cromwell, June 2, 1958; Willie O. Byrd, July 6, 1958. Fr. Pierre LeJay (not a member), who was in the United States for the ICSU meeting early in October 1958, died October 11, 1958, en route home.

Finances—Below is a brief statement of our assets as of October 1, 1958, in comparison with the last two years.

	Oct. 1, 1958	Oct. 1, 1957	Oct. 1, 1956
Cash balance	$9,097	$17,728	$18,216
* Permanent Fund	15,000	14,055	13,075
Emergency Fund	1,000	1,000	1,000
T. M. & E. Award Fund	1,335	1,288	1,268
Russian Translation Fund	11,188	40,067	...
† Conference on Mechanisms of Precipitation Formation	25,000	...	...
Totals	$62,610	$74,138	$33,559

As noted above, the provisional budget was approved by the Executive Committee by mail ballot. This was essentially the firm budget based on our own funds and an anticipated grant of funds to help us meet our current deficit. The budget necessarily had to be incomplete because of the incomplete plans for the new journal and the lack of knowledge of the size of the grant which we ultimately will receive from the National Science Foundation. The Budget Committee has now reviewed the budget in the light of informal word received from the National Science Foundation on these matters. The framework of the approved provisional budget covers the essentials for our normal operations, taking into account the $2.00 increase in dues approved by the Executive Committee beginning January 1, 1959.

A financial statement for the year ending last June 30 has been submitted to the Audit Committee and will be presented for action at this meeting.

Office staff and jobs—Our office staff consists of full time members as follows: James J. Capello, Ethel G. Sanders, and Carol Cameron Akers, under the direction of Waldo E. Smith, Executive Secretary. Part-time staff members include Glenda Quinn Olmstead (about half time) and Barry Modlin (a student whose time is variable depending on the pressure of his school work). In addition, we have the full-time services of an Antioch College student, R. Patrick Conner, who began working on July 28 and will continue through the balance of this year. Mrs. James A. Peoples, Jr., is being employed as full-time editorial assistant to the co-editors, as noted above, to look after the affairs of the JGR editorial office established at Lawrence, Kansas.

Quarters—We are now occupying six rooms at the American Association for the Advancement of Science, having added on October 1 a small room to take care of additional space required in connection with the new publication plan, the work on the Russian translation project, and in connection with other grants. Our lease expires June 30, 1959; well before that date we will enter into negotiations for continuation if this is possible. Rental rate will probably be $4.75 per square foot per year instead of $4.00 as at present.

International matters—The Committee on International Participation (J. W. Joyce, Chairman) will make a separate report on the international situation. The report of this Committee was published in the August 1958 issue of the *Transactions* (pp. 765–766) and has elicited no comment from the membership except a communication from B. F. Howell, Jr., immediately following the presentation of the report at the Executive Committee meeting last May. It is anticipated that the Chairman will offer further recommendations for action.

We understand that the Finns are progressing with plans for the Twelfth General Assembly of IUGG to be held at Helsinki, Finland, July 25 to August 9, 1960. We should begin actively to prosecute our plans for participation, and some Sections, in fact, have taken steps to set up committees to monitor spontaneous papers.

---

* Does not include accumulated interest on $2368 of U. S. Savings Bonds. The mature value of these bonds is $3200, $2500 of which mature December 1, 1958. Unless there are other instructions from this Committee, this amount will be added to one of our building and loan accounts at the time of maturity.

† Report on this item is given under Meetings below.

A general assembly of the International Council of Scientific Unions was held in Washington, October 2-6, 1958, and will be reported on later.

Meetings—It was deemed that the annual meeting held May 5-8, 1958 was an outstanding success. Our registration totaled 1249. Plans are developing for the Fortieth Annual Meeting to be held May 4-7, 1959.

The Pacific Northwest Regional Group will hold its annual meeting in Portland, Oregon, November 13-14, 1958. Vice President Berkner had planned to attend this meeting and to address an evening session on the subject "Scientific exploration of space." Berkner expects to go to the Antarctic early in November, and has made arrangements with W. H. Pickering of the Jet Propulsion Laboratory to speak on the same subject. Taking the place, as he will, of the Vice President, it is anticipated that AGU will defray his expenses unless objection is offered here.

The Section of Geodesy has established a Committee on Geodetic Applications of Artificial Satellites, and is planning a Conference on Contemporary Geodesy to be held at Cambridge, Mass., in the first week of December 1958. On June 24, after the plans for the conference had taken form, an application for a grant was filed with the National Science Foundation. The original application included about $7000 for the participation of foreign scientists, but in consultation with the Foundation this factor was eliminated, reducing the grant application to about $6800. We have informal word that the grant will be forthcoming in due course, and plans are proceeding.

The AGU is joining Section O (Agriculture) of the AAAS in the sponsorship of a symposium on water at the meeting of the AAAS in Washington between Christmas and New Year's, and also the U. S. National Committee for IGY on sessions related to the work of the IGY.

The annual meeting of the Pacific Southwest Regional Group will be held at Stanford University, February 5-6, 1959.

The Committee on Cloud Physics of the Section of Meteorology has had plans for a second conference under study for some time, and recently the National Science Foundation has approved a grant of $25,000 to cover the cost of the conference plus the cost of publication of the results presumably as one of the monograph series.

Statutes and By-Laws—As noted above, the ballot concerning the changes in the Statutes was mailed out on August 11, and the ballots were tallied on September 15 by the Committee of Tellers. Concomitant changes in the By-Laws were tentatively approved at the Executive Committee meeting on May 4, 1958, published in the August issue of the *Transactions* in accordance with the requirements of the Statutes, and are now to be placed before the Executive Committee for final action to effectuate the changes. Recommendation will be made later for this action.

Nominations—Nominating Committees for the Union and the Sections have completed their work, and the reports of all will be given later. The nominations for Union officers have been presented informally to the President of the National Academy of Sciences for concurrence or comment, and word of approval has been received.

Geophysical abstracts—President Ewing has appointed John Lyman (Chairman), Werner A. Baum, J. W. Joyce, John C. Reed, and Arthur H. Waynick as a committee to study the problem of abstracting geophysical material and seeing how this may tie in with the general programs of abstracting, both on the national scene and on the international scene, that are now under consideration. A report will be presented later.

Metric system of measure—At the meeting of the Section of Geodesy last May a resolution was passed relative to the adoption of the metric system by the United States, and it was reported at the business meeting of the Union subsequently as a resolution of the Section. In response to this, President Ewing has appointed Floyd W. Hough as Chairman of a Committee on Adoption of the Metric System in the United States to study the desirability of taking positive action to replace eventually in the United States the present English system of weights and measures and to substitute therefor the Decimal or Metric System.

American Geological Institute—Our representatives on the Board of Directors of the AGI are now James R. Balsley, Jr., and Walter H. Bucher.

Office of Critical Tables—George R. Tilton has been designated by President Ewing to serve as our representative on the Advisory Board of the Office of Critical Tables.

Miscellaneous—At the meeting of the Executive Committee on May 4, proposals were offered independently by Earl G. Droessler and Gerald J. Miatech that a suitable memorial be established in honor of the memory of Father James B. Macelwane, S.J., who at the time of his death was President of the AGU. President Ewing has appointed Droessler to explore this matter and report back with the possible result of the establishment of a formal committee.

Before the second session of the 85th Congress, the proposal for the establishment of an Institute of Geophysics in Hawaii again became active. AGU had been among the early proponents of the establishment of such an Institute, and upon reactivation of this bill in Congress a number of letters were written by the General Secretary and the Executive Secretary in the interest of the passage of the bill. The bill, however, was not passed and will be before the next Congress. It is hoped that action might be taken by that Congress to establish this greatly needed scientific facility.

The AGU also sent its endorsement of H.R. 13247, a bill in support of education in science through fellowships, scholarships, loans, and other means.

The Union was invited to send representatives to various functions during this interval, including the inauguration of the seventh President of the University of Southern California (George Tunnell of UCLA designated), the inauguration of the new President of Lafayette College (James L. Dyson, our representative), the inauguration of the twelfth President of Rensselaer Polytechnic Institute (Roland Beers designated), the inauguration of the fourteenth President of Wagner Lutheran College, the inauguration of the third President of Queens College in New York, and the dedication of Purdue University's new Memorial Center.

John R. Coash, Paul M. Pepper, Howard J. Pincus, and C. Warren Thornthwaite served as our representatives at the Second Bowling Green Conference on

Education and Professional Standards held at Bowling Green State University in Ohio on June 24–28, 1958. One of those attending (Thornthwaite) is a member of our Committee on Education.

AGU has responded to inquiries from educational and other institutions and individuals with regard to various matters pertaining to geophysics, in many cases with respect to educational facilities available and to the scope of geophysics.

A. Nelson Sayre, *General Secretary*

Action on the General Secretary's report—The report was accepted.

With regard to the maturing of $2500 worth of U. S. Savings Bonds Series F, the full confidence of the Executive Committee was expressed in the General Secretary and his advisors to invest this money in accordance with their best judgment.

With respect to the fact that W. H. Pickering of the Jet Propulsion Laboratory of the California Institute of Technology will take the place of Vice President Berkner in addressing the Pacific Northwest Regional Meeting in Portland, Oregon, November 13, 1958, it was approved that AGU should pay Pickering's expenses.

(President Ewing arrived at this point and presided for the rest of the meeting.)

Reports of Standing Committees

International Participation—Chairman J. W. Joyce gave the following information:

The third meeting of the Bureau of the International Union of Geodesy and Geophysics held at Moscow on July 21–24, 1958, is reported in some detail in *IUGG Chronicle 13.* There were 17 items on the agenda. He noted that General Secretary Laclavere announced that 1500 copies of the Toronto Assembly Transactions have been printed and that about 500 are being distributed.

The following remarks highlight and supplement the official IUGG minutes of the Bureau meeting.

As far as new memberships in IUGG are concerned, most of the remaining countries that may apply will probably be in the lower categories, with the exception of Red China. It looks as though Bulgaria will soon apply for adherence. As far as Chinese adherence is concerned, J. Tuzo Wilson, President of IUGG, visited the two Academies of Sciences of Peking and Taipei and reported briefly to Laclavere, Deacon, and Joyce during the Washington meeting of ICSU early in October 1958. He stated that if the Taipei application made it clear that it claimed to represent only the territory now controlled by the government of the Republic of China, the application which is now before the IUGG will in all likelihood be processed, but this might not be done until the General Assembly in 1960. Red China will apparently not submit an application as they refuse to sit down with "the other China." Laclavere plans to visit the two Academies in October 1958.

The *Chronicle* seems to be going over fairly well. Laclavere has received over a thousand replies to a questionnaire sent to its recipients, and practically all of them welcome it and some suggested improvements. In general, most of the instructions that were received as a result of the questionnaire and earlier meetings have been carried out. Every effort is being made to cut costs, and it will now cost about $3000 a year for printing, distribution, etc.

The IUGG Committee on Geophysical Bibliographies that was set up has not been able to meet as yet because of the wide geographical distribution of its members. Ray K. Linsley has agreed to serve as Chairman. If the AGU's committee on this subject has anything of interest to suggest, it should get into touch with Linsley so that he can take advantage of it. Joyce suggested that Linsley might well be a member of the AGU Committee on Geophysical Abstracting.

With regard to publication, the IUGG would like to try a few other publishers competitively in addition to Pergamon Press before deciding on any one.

The new categories adopted at Toronto will result in some additional revenue. IUGG will receive approximately $44,000 per year, as compared to ICSU's annual income of about $45,000.

The Bureau was not called upon to take any action on the draft text of the new Statutes and By-Laws other than to make additional suggestions.

The rules for symposia prepared by Joyce were discussed at Moscow, and after some modifications and additions by the Bureau, these are being sent to the members of the IUGG Executive Committee for their consideration. A list of 12 symposia is being considered for the Helsinki Assembly. Berkner expressed the view that IUGG has been spending a lot of money in publication and not getting enough in visible results. He urged that the AGU Executive Committee strongly support the Chairman of our Committee on International Participation, who is also on the IUGG Bureau and Executive Committee, in trying to improve the publication situation.

With regard to the Russian proposal for the establishment of award medals, Joyce noted that it is now agreed that two medals should be decorously bestowed at each General Assembly to two scientists for outstanding scientific work in geodesy and geophysics, one concerning the solid Earth and the other the hydrosphere and atmosphere.

There has been a considerable amount of discussion in the Bureau as to what the function of the IUGG should be at the close of the IGY. So far, the only concrete proposals are concerned with the holding of appropriate symposia and that the IUGG would serve as a point of coordination for possible future programs. If any AGU members have suggestions in this connection, it was urged that these be passed on to the Chairman of the Committee on International Participation for forwarding to the IUGG.

Attempts will be made to firm up agenda for the Helsinki Assembly well in advance of the opening date. The Finnish Committee is doing all it can to plan a good assembly. The IUGG Bureau has tentatively suggested that a registration fee be charged for all persons attending, at the same time cutting down social functions as much as possible to conserve funds.

The Finance Committee has indicated a possible deficit of about £25,000 for the triennium largely because of publication costs. This is based on Association and Union estimates recently received.

The next meeting of the Bureau will be held in Paris in September 1959. The Executive Committee and Finance Committee will both meet at the same time.

Chairman Joyce, in closing his remarks, reported that the report of the Committee regarding the recommended revision of the structure of the Executive Committee of the AGU to provide more effectively for the discharge of responsibilities as the U. S. National Committee for the IUGG, published in the August 1958 issue of the *Transactions* (pp. 765–766), elicited comments from only one person, B. F. Howell, Jr. Joyce is discussing his proposals with Howell to include those that are appropriate.

C. A. Whitten referred to an invitation on behalf of AGU to the International Association of Geodesy to hold a symposium on distance measuring equipment in Washington, D. C., during May 1959 in conjunction with the Annual Meeting of AGU. A motion was passed that the Executive Committee strongly endorse this plan and give any assistance that the AGU can.

Vice President Berkner reported that at the ICSU meetings two alternative attitudes were evident concerning termination of the IGY. (1) The IGY was organized and conducted with the encouragement of the Unions to obtain basic scientific data needed for the advance of geophysical sciences, these data were now amply coming in, in response to the expression of need by the Unions, and the Unions were amply competent to deal with the data through meetings, discussions, symposia, and publication. (2) The IGY organization should be continued to deal with the data. If, however, substantially all new data were handled outside of the Unions, the future usefulness of the Union comes into doubt.

Therefore, this difference in views raises a serious question as to whether the Unions should be strongly supported, or should disappear in favor of special committees. It was finally decided that there should be a Special Committee for Inter-Union Cooperation on IGY Results. International Geophysical Cooperation in research during 1959 (IGC-1959) will be continued under this Committee, but it was decided to close the IGY office late in 1959 so that this Committee would not be encouraged to act in place of the Unions. If we are going to have special committees, they should come, do their job, and then disappear. Berkner thought it would be appropriate if the Executive Committee of the AGU recognized the IGY meeting which is now planned for Washington in September 1959 as a series of symposia on IGY results and that AGU should act as one of the sponsoring agents of these symposia. He suggested that the Committee on International Participation communicate with General Secretary Laclavere and with the local arrangements committee, and make such arrangements as necessary to make the AGU a cosponsor of these symposia.

A motion was adopted that AGU, acting on behalf of IUGG, join enthusiastically in the sponsorship of the symposia dealing with IGY data to be held in Washington in September 1959 and that the Chairman of the Committee on International Participation be designated as a representative of the Executive Committee in making this arrangement.

Berkner reported that each Union is now required to designate a fixed representative to ICSU over any interval of three years. The Executive Board of ICSU has now become a permanent board operating between meetings.

ICSU has adopted a policy of political non-discrimination, that is, ICSU will recognize any *bona fide* academy, research council, or national committee in any area in order to bring all of the world into the field of ICSU and its Unions.

W. W. Atwood, Jr., referred to a provisional report on the recent ICSU meeting, a copy of which he had turned over to Berkner. This 28-page mimeographed report will be quite useful to all who are concerned with ICSU and its Unions, particularly as it contains quite a number of the reports and actions taken by the Executive Board at the meeting and perhaps would not appear in the actions of the assembly as such. Berkner asked that copies be supplied to all members of the Executive Committee.

The Executive Secretary noted that we have before us the report of the Committee on International Participation published in the August 1958 issue of the *Transactions* (pp. 765–766) and inquired as to what is the next step towards implementation of this report. It involves substantial reorganization of AGU, especially the constitution of its Executive Committee.

Joyce said that one of the principal points raised in Howell's comment was that the membership of the Council as proposed was not sufficiently under the control of AGU, and therefore his Committee should reconsider the status of the various members that have been proposed. Joyce felt that the various units that are represented on that Council are appropriately there, and the question is which should be voting members and which non-voting. He suggested that the three Government agencies listed as voting members now be removed from this, which would leave only the members at large to be appointed by the National Academy which might be quite apart from AGU. Since these would probably be selected by the Division of Earch Sciences, it was felt that AGU would in all probability have members in all this representation.

Berkner suggested that it would be proper to instruct this Committee to consult with Howell and re-draw the paper, and then see if it would meet the approval of the Research Council, with the object of circulating a final paper.

L. T. Aldrich stated that the report which we had from the Committee last spring should include the alternative when presented before the membership.

President Ewing noted that, since this is a matter which some people think is the most important function of the Union and there is so little comment on it, Howell and Aldrich serve as consultants to the Committee. This was agreed to.

Editorial and Publication—Chairman Sayre stated that this Committee will continue until the new publication plans have been implemented.

Peoples called attention to the promotional leaflet announcing the new monthly *Journal of Geophysical Research* which will be inserted immediately inside the front cover of the October issue. He expressed the belief that the improvement in the new journal will be gradual rather than sudden.

Abelson reported that things have been running smoothly with the new journal as the editors have simply accepted the reviewed material of both *JGR* and AGU. The big problem now is to see that the good material comes to the journal and that we should all be on the lookout for suitable material.

The Executive Secretary noted there will be a report of the Committee on Budget a little later relative to publication. Applications for grants have been filed with the National Science Foundation in this connection, one covering a deficit of $15,000 for the current calendar year and another covering a series of grants totaling about $237,000 over a five-year period. We have informal word that the National Science Board has approved a substantial grant for the first two years plus our deficit, which we should receive soon. We have proposals from three printers for printing the new journal, and it is expected that a decision with regard to the printer will be made in ample time so that the January issue will be on time.

Monograph Board—President Ewing noted that he is seeking a Chairman for the Monograph Board.

Berkner noted that some monographs of excellent quality frequently must have extensive illustrative material that is costly to print, causing publishers to avoid them, and that these might be undertaken by AGU in the monograph series to ensure publication. The Executive Secretary mentioned three projects that are now developing, but that formal application for a grant for the Monograph Series has yet to be filed with the National Science Foundation. Before the National Science Foundation will seriously consider making such a grant, we need to have the Monograph Board formally appointed and some actual plans for monographs that we want to put into this series. Ideas for definite monographs were requested. Landsberg noted there is no oversupply of good material and felt that if AGU would use its monograph series as an integral part of things presented at AGU meetings and conferences, being sure that the quality is excellent, then the monograph series would provide an excellent and prompt outlet. Abelson noted that the Monograph Board should be largely a policy-making group that would have to have energy to seek out the best advice on a prospective monograph and select the proper technical editor for each.

The meeting recessed at 10h 40m and was resumed at 11h 00m.

Russian translation project—It was noted that Nos. 1 to 5 and 7 of 1957 of *Izvestiia* have now been received, No. 7 only within the last two or three days. On October 16 a conference was held by the General Secretary and the Executive Secretary with I. R. Maxwell and D. J. Raymond of Pergamon Press, and with Paul S. Feinstein of the National Science Foundation sitting in. At this meeting the difficulties and delays were reviewed, it being pointed out that AGU is dissatisfied not only with the increasingly delayed delivery schedule but also with respect to the quality of the translations although there has been some improvement in recent numbers. Maxwell made the following proposition:

"1. Pergamon Press is willing and able to continue to translate and issue this journal for and on behalf of the American Geophysical Union.

"2. Recognizing the dissatisfaction because of late delivery of the 1957 issues which were wholly and completely due to lack of skilled and experienced translators in the area and translation editors and because the Russians increased the journal by some 30 pct, that is, approximately 500 additional pages, and realizing that in spite of this Pergamon Press has been at fault formally in that the issues have been late, Pergamon Press proposes that the arrangements from 1958 be predicated on the following special conditions in addition to the usual contractual arrangements that may be required:

"(a) The Russian Translation Board and Pergamon Press to agree on a publication schedule for the issues of 1958. However, the Russian Translation Board may, in the absence of agreement by Pergamon Press, fix such time schedule as it considers reasonable for the publication of these issues.

"(b) Pergamon Press will accept a penalty clause of $500 for each issue that it may be late in issuing in accordance with the publication schedule laid down or agreed upon with the Russian Translation Board. This penalty clause is automatic if any issue is more than 30 days late after a stipulated date with the Committee.

"(c) AGU may terminate this contract without advance notice at any time that Pergamon Press fails to publish any issue within the date plus 30 days agreed or stipulated by the Russian Translation Board.

"(d) In the event of AGU exercising the right of cancellation, Pergamon Press agrees and warrants the orderly handover of all subscription records, the translations in the pipeline, illustrations, and do all such things as they may be required to do by the Russian Translation Board of the AGU to ensure the continued publication of the journal with a minimum of dislocation, effort, or expenditure on behalf of AGU.

"(e) Pergamon Press is making this offer to AGU because they believe that the know-how and experience that they have acquired in the past year is too valuable a translation asset in this area for it to be thrown away and discarded. We firmly believe that AGU will be completely satisfied with the translation and the speed that is being made available for 1958, and, in addition, should this not prove to be so and should AGU wish to take on the job itself, then this arrangement would give the necessary time to set up an alternative mechanism for doing the job better and quicker than it has been hitherto."

General Secretary Sayre, in reviewing the Pergamon Press difficulties, indicated that Maxwell had noted that they have had a great turnover in translators, using as many as 200, that at the present time his stable of translators is operating satisfactorily and the translations for 1957 are complete, and that without authorization Maxwell has started the translation of *Izvestiia* for 1958. Sayre, indicating that he neither espoused nor rejected Maxwell's proposal, felt that we should give it due consideration, taking account that if we undertake this ourselves we will probably have to go through much the same difficulties that Pergamon Press has found. Pergamon Press feels that their performance on this endeavor has given them a bad name and that they would like to have opportunity to overcome this by better performance in respect to *Izvestiia* for 1958. It was pointed out that an essential thing of the memorandum is a penalty clause of $500 for late issues and also the termination clause if the project does not develop in a satisfactory way. After extensive discussion, especially with regard to quality, it was felt that we could set up our own project with a translation editor and stable of translators in much the same way as the American Institute of Physics has set up their project for the *Journal of Experimental and Theoretical Physics* with J. George Adashko as their translation editor. In this connection we will seek the concurrence of the Russian Academy of Sciences and make an effort to secure originals of figures in order to improve reproduction. Vice President Berkner noted that he feels that AGU should not embark upon anything that will in any way jeopardize our new *Journal of Geophysical Research* and the Monograph Series.

A motion was made and passed unanimously that it is the sense of the meeting that the Russian Translation Board should make all possible efforts to use another translation agency for the 1958 *Izvestiia*.

Budget—Chairman John C. Reed presented the report of the Committee on Budget as set forth in Appendix 1. Noting that this now involves the numerous developments that have taken place since the provisional budget was submitted to the Executive Committee in early July, the budget as set up contemplates a grant from the National Science Foundation for publication of the *Journal of Geophysical Research* which actually is not yet in hand but which should be received at least in large measure according to informal advice received.

Nominations—Chairman L. H. Adams noted that the rule concerning the number of nominees was suspended for the elections of 1956 by a mail ballot of the Executive Committee during July. He offered the following nominations for and on behalf of his Committee for the three-year period commencing with July 1, 1959: For President, Lloyd V. Berkner; for Vice President, F. W. Reichelderfer and George P. Woollard; for General Secretary, John Lyman and A. Nelson Sayre. The report was accepted.

The following nominations were submitted by the Committees on Nominations of the Sections for the three-year period starting July 1, 1959:

Geodesy—Charles Pierce for President; Floyd W. Hough for Vice President; Buford K. Mead for Secretary
Seismology—L. M. Murphy for President; J. A. Peoples, Jr., for Vice President; B. F. Howell, Jr., for Secretary
Meteorology—Thomas F. Malone and B. Haurwitz for President; Gordon E. Dunn and E. W. Hewson for Vice President; Woodrow C. Jacobs for Secretary
Geomagnetism and Aeronomy—L. R. Alldredge for President; C. T. Elvey for Vice President; J. H. Nelson for Secretary
Oceanography—John Lyman and Walter H. Munk for President; Arnold Arons and D. W. Pritchard for Vice President; Eugene C. La Fond and Dale Leipper for Secretary
Volcanology, Geochemistry, and Petrology—Alfred O. C. Nier for President; Francis J. Turner for Vice President; Irving W. Friedman for Secretary
Hydrology—Harry F. Blaney and Walter B. Langbein for President; Wm. C. Ackermann and William E. Hiatt for Vice President; Charles C. McDonald and Ralph N. Wilson for Secretary
Tectonophysics—Patrick M. Hurley for President; L. B. Slichter for Vice President; H. Richard Gault for Secretary;

President Hess of the Section of Tectonophysics noted that there are no nominees for two members of the Section's Executive Committee and that he will arrange with the Committee on Nominations of the Section to make them.

The nominations submitted were accepted.

The following nominations were submitted by the Committee on Nominations of the two regions cited for the three-year period commencing July 1, 1959:

Pacific Northwest Regional Committee: Representing Geodesy—Donald J. Brown and Ector B. Latham; representing Seismology and Tectonophysics—Mark F. Meier and Peter Misch; representing Meteorology—Lenard Bissell, Carlton Jencks, Donald W. Keuhl, and Melvin J. Ord; representing Geomatism and Aeronomy, and Volcanology Geochemistry, and Petrology—Keith E. Anderson and Peter B. Boyer; representing Oceanography—Nedevia Bethlahmy and Wayne V. Burt; representing Hydrology—Charles L. Barker, Thomas H. Campbell, Harold D. Hafterson, Albert M. Moore, Calvin C. Warnick, and R. A. Work.
Pacific Southwest Regional Committee: Representing Hydrology—Arthur F. Pillsbury, Joseph F. Poland, and David K. Todd; representing Oceanography—Henry W. Menard and Jacob B. Wickham; representing Meteorology—W. D. Duthie, Eugene Bollay, and Robert E. Holzer; representing Geomagnetism and Aeronomy—E. H. Vestine

The recommendations for the Regional Committees were accepted.

The Executive Secretary reported that no nominations have been received from the North Central Regional Committee and that perhaps we should consider this Region as no longer operative if no nominees are received by June 30, 1959, as it has not been active for some time.

Statutes and By-Laws—A motion was passed taking final action to approve the changes in the By-Laws approved at the Executive Committee meeting of May 4, 1958, and published in the August 1958 *Transactions* (pp. 764–765).

A suggestion was made to change the Statutes to eliminate the present provision that non-citizens of the United States can not vote. Action on this was postponed pending the receipt of a report from the Committee on International Participation.

Meetings—Chairman P. H. Abelson announced that President Ewing would be expected to present a presidential address on the evening of the Bowie Medal Award at the Annual Meeting. He also noted that the Committee always welcomes suggestions with regard to plans for the meetings.

The Executive Secretary reported that there are recurring inquiries from members as to why the Annual Meetings are not held in other cities. Other members have asked whether we could arrange the meetings so that they are entirely under one roof. These questions should constantly be kept before us. With regard to meeting under one roof, this would mean going to a hotel, which would involve luncheons, dinners, and other functions and frequently not too intellectual an atmosphere. The feeling was that we should continue to hold our meetings with headquarters at the National Academy of Sciences.

Membership—Chairman Earl G. Droessler was not present but had indicated that he had no report other than that shown by the membership statistics in the General Secretary's report. Vice President Berkner called attention to the substantial increase in corporation memberships, most of which were the result of about 20 letters that he sent out in the spring. He urged others also to write letters to their friends in key positions in industrial and commercial concerns that are involved in any way in geophysics.

The suggestion has been made that, in addition to corporation membership at $100 a year, we might have other memberships such as sustaining memberships and contributing memberships, say, at $1000 and $500 a year. A motion was adopted that the Committee on Statutes and By-Laws take steps to make amendments in the Statutes and By-Laws for provision of such memberships as these, the report to be brought in at the next meeting of the Executive Committee.

Audit—The report which Chairman A. G. McNish submitted on behalf of the Committee on Audit as set forth in Appendix 2 was accepted.

Reports of Special Committees

Cosmic-Terrestrial Relationships—Chairman E. H. Vestine was not present, but it was noted that a recent report has been submitted by him. This is now in the hands of the editors of the *Journal of Geophysical Research* to decide whether it is proper material for that journal or whether it should be published in the *Transactions.*

Award of William Bowie Medal—Chairman Walter H. Bucher reported that the Committee has selected Walter M. Elsasser as the Twenty-First Recipient. This report was accepted. It was noted that plans are being made for a dinner preceding the formal award of the Medal on the evening of May 5, 1959, and that this dinner will probably be held at a hotel as in the spring of 1958.

Tellers—Chairman J. H. Nelson submitted the report of the Committee with regard to the recent ballot on changes in Statutes as indicated in Appendix 3. President Ewing expressed great satisfaction to find that so large a number voted so strongly in favor of the new publication plans.

Education—President Ewing reported on behalf of Chairman John E. Nafe who could not attend, and noted that attempts to hold meetings of this fairly large committee have not been successful, that the Chairman had circularized the members to determine whether they would rather disband or have a smaller committee and found the vote was indecisive, and that he requested instructions as to what should be done. Hess, a member of the Committee, noted that the Committee has never been able to get together to define exact objectives and that the present broad scope makes the Committee rather ineffectual. The President requested comments from those who felt that this group has useful work to do. Langbein mentioned that there is no unified training in hydrology, that it is now on-the-job training, and that he felt AGU might be of some help. The Executive Secretary gave a brief history of our endeavor in this regard, noting that this was the outgrowth of frequent inquiries to the office for information and that it stems back originally to the survey made in 1945 and published in the December 1945 issue of the *Transactions*, with a supplement in August 1946, Geophysics is a late comer, is rather diffuse on most college campuses. The National Science Foundation felt that our plan for a new survey on education in geophysics, rather similar to the 1945 plan, was superficial and that we should go more deeply into the problem, citing the work that the mathematicians had done in relation to the graduate education in mathematics. Atwood referred to the success of the educational programs of IGY. W. C. Jacobs expressed the thought that it is important that AGU be equipped to advise on these matters, noting that the Air Force has a good program on training officers in the broader aspects of geophysics and that AGU would be a logical Air Force contact if we had material available that would be of help. Berkner noted a substantial sentiment in universities to reorganize training in the Earth's sciences and that there has been some pulling together of the geophysical sciences, perhaps to a certain extent under the influence of the IGY. He felt that we need a high-level man to undertake a survey like this, one with enthusiasm to head up such a committee and work with schools that are reorganizing their courses. He mentioned certain names that might well be sought. Peoples noted that at the undergraduate level the emphasis for most fields of geophysics should be on mathematics and physics rather than on geophysics but that in geophysical engineering this might not be necessary. Berkner expressed the thought that mathematics should draw its problems from the field in which the student is specializing, and that mathematics should appropriately be developed around geophysical problems. Howell suggested we should find out how members of the Union had entered geophysics as a profession, noting that relatively few are trained as geophysicists. Hurley mentioned that he is also a member of the Committee on Education and is involved in the work at the Massachusetts Institute of Technology in building up geophysics there, and he has the feeling that a questionnaire will serve no useful purpose. He indicated that MIT is developing a monograph series for supplementary reading for education in high schools to orient students who have natural interest or inclination in geophysical curricula. His feeling was that the Committee should disband. Peoples suggested that it would be helpful if this Committee could put out a brief report on what universities like MIT and Princeton have done to unify geophysics on our campuses. Abelson expressed the thought that a good deal depends upon the man who is Chairman. If we find one who feels that something useful can be done, have him go ahead; if not, the Committee should be disbanded. No action was taken.

Geophysical Abstracts—Chairman John Lyman was absent, and John C. Reed, a member of the Committee, reported on his behalf. He noted that the Committee has prepared a report on which they sought the cooperation of the American Meteorological Society. This would involve an expansion of the present *Meteorological Abstracts* to become *Meteorological and Geo-*

physical Abstracts. We might become cosponsors and lend moral support and aid in securing grants and other funds for support but leave the administration of the project in the hands of the American Meteorological Society with a joint cooperating committee. No report has yet come in from the AMS on this plan. The report of the Committee appears in Appendix 4.

Adoption of the Metric System in the United States—Chairman Floyd W. Hough noted that this is a new Committee and is just becoming organized.

Macelwane Memorial—It was noted that this is not a formal committee but simply a move in which President Ewing and Earl G. Droessler are joining to see what might be undertaken.

Reports of Sections

Geodesy—Vice President Charles Pierce noted that President Schmidt has no formal report but mentioned that the Committee on Geodetic Applications of Artificial Satellites has arranged a Conference on Contemporary Geodesy to be held at Cambridge, Massachusetts, December 1 and 2, 1958, with the cosponsorship of the Smithsonian Astrophysical Observatory and Harvard University. AGU expects a grant from the National Science Foundation in the amount of $6800 to aid in defraying the costs of this conference and the compiling and publication of the record.

C. A. Whitten again referred to the symposium to be held by the International Association of Geodesy on distance measuring equipment in Washington, D. C., in conjunction with the Annual Meeting, and AGU's responsibility to help to make it a success. He noted that a group met in Munich, Germany, last July for the establishment of a Committee on Earth Tides sponsored by the International Association of Geodesy and the International Association of Seismology and the Earth's Interior. W. D. Lambert, who attended the meeting in Munich but who was not present, has raised the question as to what extent other Sections, notably Oceanography and Hydrology, might be interested.

Meteorology—President Landsberg announced that the Committee on Cloud Physics of the Section is arranging a Conference on the Mechanisms of Precipitation Formation which will be held in June 1959 at the Woods Hole Oceanographic Institution. A grant of $25,000 has recently been received in support of this conference to bring foreign participants and to compile and publish the results.

Oceanography—Secretary D. W. Pritchard mentioned the International Congress on Oceanography which is to be held in New York in September 1959.

Hydrology—W. B. Langbein, alternate for President Linsley, noted that the international symposia of the International Association of Hydrology had been outstandingly successful and that these give an opportunity to become more acquainted with developments in specific fields than the reports presented at the general assemblies. The Darcy symposium held in France in 1957 and the one held in Chamonix, France, in September 1958 on the physics of ice movement were excellent. A symposium on forests and waters will be held in Germany in 1959. The Association is rather hard put financially with regard to publication. The publications do not receive as wide circulation as they should. The Association is issuing a quarterly bulletin on hydrology which they feel should help to overcome this difficulty.

National Research Council reports

It is now noted that Frank Press is the representative of AGU in the Division of Earth Sciences and that John N. Adkins is Chairman.

New Business

The General Secretary noted that presumably we will soon receive a substantial grant from the National Science Foundation to aid in our publication plans, and requested instructions as to where this money should be deposited to be most safe. Our present arrangement is to put our excess funds in the savings account in the Riggs National Bank, but these are not guaranteed or insured beyond $10,000. Many building and loan associations, both in the Washington area and elsewhere, are paying interest up to four per cent, but they are guaranteed only to the extent of $10,000 each. Budget Chairman Reed suggested putting this money in Government bonds as the guarantees elsewhere are not adequate. Vice President Berkner felt that we should investigate the possibility of purchasing 90-day or similar Treasury notes for monies needed at an early date that carry interest from one to three per cent, that can be cashed at any time, and that do not flucuate in value. A motion was adopted instructing the General Secretary to invest such monies as seem appropriate in Goverment bonds or Government guaranteed deposits, and, for monies needed at an early date, in 90-day or similar Treasury notes.

The Executive Committee expressed its appreciation for the work done by the two coeditors of the new journal, P. H. Abelson and James A. Peoples, Jr., and the Executive Secretary in getting the new publication plans under way.

Adjournment—The meeting adjourned at 13h 15m.

A. Nelson Sayre, *General Secretary*
Waldo E. Smith, *Executive Secretary*

Appendix 1—Report of the Committee on Budget for the Fiscal Year Ending June 30. 1959

John C. Reed, Chairman
E. H. Bramhall L. O. Quam

Your Budget Committee prepared a provisional budget for 1959 that was presented to the Executive Committee on May 4, 1958. Because of actions of the Executive Committee in regard to dues, publications, and other items, that first budget for 1959 required substantial revision. A revised budget was laid before a meeting of some of the officers of the American Geophysical Union on June 18 by Bramhall and that revision, with one minor change, was sent to the Executive Secretary on June 26. It was approved as a provisional budget by the Executive Committee in July.

Events since June make possible another revision of the budget now with fair assurance that some heretofore doubtful areas are stabilized. However, some of the developments that greatly affect the budget have happened so recently that the Chairman of the Budget Committee has not had an opportunity to consult with the Committee in regard to them.

Thus the revised budget here presented is, in respect to the latest changes, entirely the responsibility of the Chairman.

Regular Operations

Estimated receipts

Membership dues			
4100 members at $10	$41,000		
100 student members at $3	300		
23 corporation members at $100	2,300		
Dues in arrears, 500 members at $8	4,000	$47,600	
Publications			
Sales and subscriptions			
Journal of Geophysical Research, 1000 at $16	16,000		
Transactions, 1000 at $4	4,000		
Sales of back numbers	1,000		
Reprints	3,000		
Page charges (½ year), 800 at $15	12,000		
Advertising	14,000	50,000	
Other			
National Research Council grant	400		
Interest on funds on deposit	3,600		
Geophysical Monograph No. 1	800		
Geophysical Monograph No. 2	5,000		
Royalties (microcards and reprinted *Transactions*)	200		
National Science Foundation grant[1]	146,000		
Miscellaneous (includes contributions to permanent fund)	500	156,500	$254,100

Estimated expenditures

Transactions of 1958 (6 mos. 3 issues)			
Preparation, proof reading, etc. (chiefly salaries)	$4,400		
Printing (3 issues at $5,500)	16,500		
Mailing	700		
Editors	700		
Reprints	1,400		
Advertising agent's commission	1,500	$25,200	
Transactions of 1959 (6 mos. 2 qtrly. issues)			
Preparation, proof reading, etc.	600		
Printing (2 issues of 24 pages each)	1,500		
Mailing	300	2,400	
Journal of Geophysical Research (6 months, 6 issues, 200+ pages each)			
Preparation, proof reading, etc. (chiefly salaries)	16,000		
Printing (6 issues)	43,560		
Cover	300		
Mailing	1,500		
Editor and assistant	3,000		
Reprints	4,000		
Advertising agent's commission	2,800	71,160	
General Office expenses			
Rent	4,300		
Salaries and Social Security	18,800		
Retirement contribution	1,200		
Stationery and supplies	2,000		
Office equipment	2,000		
Postage and communications	2,500	30,800	
Expenses for meetings			
Annual	1,500		
Regional	200	1,700	
Miscellaneous			
Expenses for Sections	100		
Expenses for Committees	100		
Travel of Officers	1,000		
President's fund	100		
Directory Reserve	1,300		
Monograph No. 2	6,500	9,100	$140,360

Total expenditures	$140,360
Total receipts	254,100
Estimated surplus[2]	$113,740

---

[1] Of the $146,000, $46,000 is estimated to be needed in fiscal 1959, $66,000 in 1960, and $34,000 in the first half of fiscal 1961.

[2] The apparent surplus must be considered in the light of the expectation that large amounts will be needed for publications in 1960 and 1961.

Appendix 2—Report of the Committee on Audit for the Fiscal Year Ending June 30, 1958

A. G. McNish, Chairman
E. B. Roberts R. H. Weightman

Your Committee on Audit has examined the books of the American Geophysical Union for the fiscal year ending June 30, 1958, and finds them in agreement with the statement of the Union's finances supplied by the Executive Secretary.

At the beginning of the current fiscal year the cash assets of the Union amounted to $80,832.25, including Series F bonds and deposits in the Permanent Fund. In addition, bills receivable amounted to $11,954.97, making the total assets of the Union $92,787.22. The liabilities of the Union, including checks outstanding, bills payable, and commitments, amounted to $54,625.02, leaving a surplus of $48,987.46. At the close of the present fiscal year the assets of the Union, including bills receivable, amounted to $77,687.38, and liabilities amounted to $31,328.08, leaving a surplus of $46,359.30. A large part of this decrease in assets resulted from expenditures against the translation project, with a corresponding decrease in liabilities. The healthy aspect of the Union's financial condition is reflected in the small change in the balance between these figures.

Your Committee has examined the books recording the financial transactions of the Union, and, although a completely detailed audit has not been made, the Committee has spot-checked the records and examined large items with sufficient care that we can assure you of the soundness of this report.

Your Committee wishes to compliment the office of the Executive Secretary for the excellent condition and meticulous detail in which the financial records have been kept. Even minor contributions by members to the Permanent Fund of the Union, many of which amounted to only $1 or $2, have been properly entered in the records of the Union with the names of the donors of these funds.

Operating Statement

(Fiscal year ending June 30, 1958)

Receipts

National Research Council grant for publication			$400.00
National Research Council grant for IUGG meeting			800.00
Income			
Dues, 1955 and earlier	$61.20		
1956	560.17		
1957	4,034.38		
1958	34,194.25		
1959 et seq.	212.08		
Corporation memberships	3,000.00	$42,062.08	
Sales of publications			
Transactions	$15,231.13		
Reprints	5,506.86

Less checks outstanding	7,408.91
	$42,409.47

Appendix 3—Report of the Committee of Tellers

The Chairman and several members of the Committee of Tellers met at the office of the American Geophysical Union at 09h on September 15, 1958 to open and count ballots. The following assortment of ballots was considered:

Total ballots received		2205
Rejected ballots:		
Ballots from non-citizens of the United States	33	
Ballots from members delinquent in payment of dues	7	
Defective ballots (unmarked)	6	46
Qualified ballots counted		2159

The result of the vote is as follows:

In favor of the change of publications plan	2081
Not in favor	78

The following members of the Committee participated in the counting of the ballots: Messrs. James N. Jordan, B. C. Byrnes, and H. G. Thomasson.

J. H. Nelson, *Chairman*
Committee of Tellers

Appendix 4—Report of Committee on Geophysical Abstracting

JOHN LYMAN, Chairman
WERNER A. BAUM JOHN C. REED
J. W. JOYCE ARTHUR H. WAYNICK

This Committee was established at the Executive Committee meeting of May 4, 1958 [*Trans.*, Aug. 1958, p. 758] to study the problem of implementing the abstracting and indexing of geophysical items. At the same meeting a motion was adopted favoring the objective of a complete geophysical abstract journal "without financial encroachment upon the regular funds of the Union."

In pursuing these objectives, the Committee has met at intervals during the summer, as far as the varied activities of its members permitted. It has learned of several projects to abstract or index geophysical items.

One is an *International Journal of Geological Abstracts* of the International Geological Congress. As currently envisioned, this journal would not cover magnetism, aeronomy, or geodesy. The prospects that it will actually commence in 1959 look slim.

Another is the *Geological Abstracts*, which the Geological Society of America is currently transferring to the American Geological Institute. This journal reproduces only authors' abstracts, and cannot be regarded as anything like a complete coverage of the field, especially outside of North American geology.

Geophysical Abstracts of the U. S. Geological Survey will be continued only until some outside agency fills the gap. It produces only about 1400 abstracts annually, far short of the estimated 8500 items that appear in the field.

Meteorological Abstracts of the American Meteorological Society prints 6000 abstracts a year in meteorology, hydrology, glaciology, oceanography, and upper atmosphere. With about 40 per cent increase in its size it could cover the entire geophysical field. We have had correspondence with the American Meteorological Society concerning a proposal to expand *Meteorological Abstracts* into such coverage of the entire field of geophysics.

This Committee, having compared the propositions described above, with the possibility of initiating a new geophysical abstract journal entirely under the auspices of the Union, feels that, in view of the manifold problems connected with the launching at this time of the monthly *Journal of Geophysical Research* and the continuation of the *Izvestiia* translation, it would be more prudent to encourage one of the other projects mentioned than for the Union to undertake an entirely independent operation. Among those listed above, the *Meteorological Abstracts* proposal appears to have the greatest merit by a very wide margin. The Committee therefore recommends that the proposal of the American Meteorological Society be endorsed by the American Geophysical Union and that a permanent committee of the Union be established to work with the American Meteorological Society on the further implementation of the basic objective.

Report on the Thirteenth Annual National Conference on Educational and Professional Standards

Note: This Conference was held at Bowling Green State University, Bowling Green, Ohio, June 24–28, 1958, under the auspices of the National Education Association. AGU's representatives were John R. Coash, Professor of Geology at Bowling Green State University; Paul M. Pepper, Assistant to the Director, Ohio State University Research Foundation; Howard J. Pincus, Professor of Geology, Ohio State University; and C. Warren Thornthwaite, Director, Laboratory of Climatology, Elmer, New Jersey. The following is a summary report prepared by Coash.

The members of the AGU delegation were in attendance at various sessions of the conference and so varying reports were received to some extent. Being at home here in Bowling Green, I was personally able to attend most of the sessions. As is the usual pattern at these education meetings, there were general sessions with speakers followed by discussion groups. The speakers aired a number of views from both sides of the fence, that is, the scholar and the professional educator. The groups then pursued, on successive days, these topics: Purposes of Education, Subject Matter Preparation, and Professional Preparation. Summaries of the discussion (by 30–40 groups of perhaps 25 people each) were then presented.

The following comments and recommendations, while not those of the entire AGU delegation, were made by one or more of our delegates, either at the conference or in more recent correspondence. The order of presentation has no significance.

(1) AGU (and other Earth Science professional organizations) should have some sort of policy to guide future delegations. It is time for constructive comments on education, on the school, and on the responsibilities or our profession.

(2) Now that the door has opened, there will probably be more meetings of this type. Cooperative meetings in many states are already planned. AGU should be ready to participate.

(3) We are informed that Earth Scientists appointed to National Committees were lax. We know that many Earth Scientists are generally lax or disinterested in promoting Earth Science in school curricula. We do not favor this viewpoint. What is more basic or more interesting to a youngster than this natural world? My own discussion group at the conference (and every other similar local group I have been in during the past several years) agreed vigorously that the natural sciences—Earth Science and Biological Science—should be fundamental, especially in the elementary school curriculum.

(4) We were disappointed to see so little time at the conference devoted to subject-matter preparation.

(5) However, the joint conference was a good idea.

We were all impressed with the idea that the professional educators were recognizing once more the importance of competence in subject matter. In at least one discussion group this was entirely agreed upon, even at the elementary level. This is surely gratifying.

(6) Funds, especially for salaries, are still our biggest drawback to education and to teacher preparation.

(7) Subject matter people should have more, and more clearly defined, authority in certifying and in setting up certification requests.

(8) Science courses, with graduate credit in education for the teacher, are badly needed. Here the Earth Scientists and AGU could offer something constructive.

(9) AGU could help by circulating or reprinting in part things such as *Education in Review* from the New York Times of July 6, 1958 and the AAAS report in progress on *Recommendations for the Preparation of High School Teachers of Science and Mathematics*.

(10) Most of the delegates felt that most everyone at the conference wanted the same things. Differences were slight and represented background rather than goals.

We most heartily endorse further participation in such conferences. Perhaps we ought to sponsor some of our own.

JOHN R. COASH, *Chairman*

Annual Meeting of the Geophysical Society of Hawaii

The Geophysical Society of Hawaii, serving as the Mid-Pacific Regional Branch of the AGU, held its annual meeting on September 30 and elected the following officers: President, Gordon Macdonald; Vice President, Nicholas Chavasse; Secretary-Treasurer, Saul Price; and Councilor, Walter Steiger. Thomas S. Austin is the retiring President. Colin Ramage's term as councilor continues for another year.

Special Announcements

List of Official Nominees for Officers of the Union, of the Sections, and of Two of the Regional Committees for the Triennium July 1, 1959 to June 30, 1962

Union or Section	President	Vice President	Secretary[a]
Union	Lloyd V. Berkner	F. W. Reichelderfer George P. Woollard	A. Nelson Sayre John Lyman
Geodesy	Charles Pierce	Floyd W. Hough	Buford K. Meade
Seismology	L. M. Murphy	J. A. Peoples, Jr.	B. F. Howell, Jr.
Meteorology	Thomas F. Malone B. Haurwitz	Gordon E. Dunn E. W. Hewson	Woodrow C. Jacobs
Geomagnetism and Aeronomy	Leroy R. Alldredge	C. T. Elvey	J. Hugh Nelson
Oceanography	John Lyman Walter H. Munk	Arnold Arons D. W. Pritchard	Eugene C. La Fond Dale Leipper
Volcanology, Geochemistry, and Petrology	Alfred O. C. Nier	Francis J. Turner	Irving W. Friedman
Hydrology	Harry F. Blaney Walter B. Langbein	Wm. C. Ackerman Wm. E. Hiatt	Ralph N. Wilson Charles C. McDonald
Tectonophysics[b]	Patrick M. Hurley	L. B. Slichter	H. Richard Gault

[a] For General Secretary in the case of the Union.

[b] Two members of the Executive Committee of the Section are to be elected also. The nominees are Clarence R. Allen and Iris Borg.

Nominees for Regional Committees (nine to be elected)

Pacific Southwest Regional Committee (Arizona, California, and Nevada)
Hydrology: Arthur F. Pillsbury, Joseph F. Poland, and David K. Todd
Oceanography: Henry W. Menard and Jacob B. Wickham
Meteorology: W. D. Duthie, Eugene Bollay, and Robert E. Holzer
Geomagnetism and Aeronomy: E. H. Vestine

Pacific Northwest Regional Committee (Idaho, Montana, Oregon, Washington, and Wyoming)

Geodesy (one to be elected): Donald J. Brown and Ector B. Latham

Seismology and *Tectonophysics* (one to be elected): Mark F. Meier and Peter Misch

Meteorology (two to be elected): Lenard Bissell, Carlton Jencks, Donald W. Kuehl, and Melvin J. Ord

Geomagnetism and Aeronomy, and *Volcanology, Geochemistry, and Petrology* (one to be elected): Keith E. Anderson and Peter B. Boyer

Oceanography (one to be elected): Ned Bethlahmy and Wayne V. Burt

Hydrology (three to be elected): Charles L. Barker, Thomas H. Campbell, Harold D. Hafterson, Albert M. Moore, Calvin C. Warnick, and R. A. Work

North Central Regional Committee (Minnesota, Iowa, Missouri, North and South Dakota, Nebraska, Kansas, and contiguous Canadian provinces)

Harry C. Bolon, Martin E. Nelson, Robert J. Pafford, Robert H. Shaw, Athelstan Spilhaus (other nominations pending)

Explanatory note—In accordance with the Statutes and By-Laws as amended, elections by mail ballot are to be held in the first part of 1959. The Committees on Nominations for the Union and the Sections were appointed as follows, with the first-named as Chairman: **Union,** L. H. Adams, Walter H. Bucher, and M. A. Tuve; **Geodesy,** A. J. Hoskinson, Gunnar Leifson, and Julius Speert; **Seismology,** Beno Gutenberg, J. E. Oliver, and Don Tocher; **Meteorology,** Sigmund Fritz, John C. Freeman, and C. L. Hosler; **Geomagnetism and Aeronomy,** J. W. Joyce, Walter M. Elsasser, Carl W. Gartlein, J. P. Heppner, and E. H. Vestine; **Oceanography,** D. E. Carritt, R. S. Arthur, B. C. Heezen, R. C. Vetter, and W. S. Von Arx; **Volcanology, Geochemistry, and Petrology,** W. W. Rubey, George R. Tilton, and O. F. Tuttle; **Hydrology,** Harold G. Wilm, Arthur Johnson, and F. J. Veihmeyer; **Tectonophysics,** Ernst Cloos, M. King Hubbert, and L. L. Nettleton; **Pacific Southwest Region,** V. A. Vanoni, Eugene Bollay, and Robert E. Holzer; **Pacific Northwest Region,** Hollis M. Orem, David Rockwood, and Robert T. Beaumont; North Central Region, Phillip Light, Carl Kisslinger, and LeRoy Scharon.

The Executive Committee of the Union has established procedures for nomination and election of officers of the Union, as published in the December 1946 issue of the *Transactions*, page 910. These are as follows: (1) Nominations shall be initiated by a small Nominating Committee consisting of three or five members, appointed by the President. (2) At least two persons shall be nominated for each of the offices of President, Vice President, and General Secretary. (Rule suspended for the elections of 1959 by action of the Executive Committee by mail ballot in July, 1958, to give the Committee on Nominations discretion as to the number of nominees it may submit for any office.) (3) Such nominations shall then be submitted by the Nominating Committee to the Executive Committee, which body may accept the report, or add other nominees for such offices. If there are other nominees, it will then proceed to select by secret ballot not less than two official nominees for each office. (4) Such nominations shall then be announced to the membership, sufficient time being provided before election to permit further nominations by petition when signed by one per cent (51 at present) of entire membership, it being mandatory that nominations by petition be added to the official nominations (see (9), below). Ballots containing official nominees and those submitted by petition shall be mailed to the active membership and such ballots, postmarked before a specified date, shall be marked and forwarded by the membership to the General Secretary. (6) The General Secretary within ten days after the specified date shall turn over all such ballots for tallying to a Committee of Tellers consisting of one member selected from each of the eight Sections and one member from the Executive Committee. (7) The Committee of Tellers shall make report to the General Secretary within ten days, showing the result of the ballot. (8) A plurality of votes cast shall elect. (9) Consent of each candidate is to be obtained before placing his name on the ballot. (10) The Sections shall be urged to adopt similar procedures.

Similar Section procedures were established and were published in the *Transactions* of December 1946, with amendments covering Seismology and Hydrology in the *Transactions* of August 1949, page 627. In the summer of 1952, the Executive Committee of the Section of Geodesy voted to permit the nomination of but one candidate for each office of that Section, and at the annual meeting of May, 1958, the Section of Tectonophysics took a like step. The procedures will not be repeated in full here. All provide for nominations by petition, the number of member petitioners affiliated with the Section being as follows: Geodesy, ten members; Seismology, 13 members; Meteorology, 25 members; Geomagnetism and Aeronomy, one per cent of those affiliated with the Section (12 members at present); Oceanography, ten members; Volcanology, one per cent of those affiliated with the Section (nine members at present); Hydrology, 25 members; and Tectonophysics, 15 members.

Please note that nominations by petition must include written consent from the nominee, to be transmitted to the office of AGU with the petition.

The following schedule for nominations and elections has been established:

By November 10, 1958, steps (1) to (3) and step (9) of procedure must be complete for the official nominees.

In Transactions of December, 1958, publish list of official nominees with explanatory note.

By February 1, 1959, nominations by petition must be in the office of AGU with written consent of nominees.

By March 1, 1959, ballots carrying names of official and petition nominees, will be mailed to the membership. A brief biographical sketch relating to each nominee will accompany, but not be a part of, the ballot.

On March 31, 1959, balloting will close. Ballots must be postmarked not later than that date and be received in the office of AGU not later than April 4, 1959, in order to be counted.

By April 10, 1959, ballots will be turned over to the Committee of Tellers.

By April 20, 1959, results of tally will be turned over to the General Secretary, results to be announced at the Annual Meeting May 4–6, 1959, and published in the *Transactions* in June, 1959.

In addition to the election of Union and Section officers, two Regional Branches will hold elections by mail ballot, the nominees to be voted upon only by members in those Regions. The names are also shown in the accompanying table.

Waldo E. Smith, *Executive Secretary*

WALTER M. ELSASSER NAMED TWENTY-FIRST WILLIAM BOWIE MEDALIST—Walter M. Elsasser, Professor at the Scripps Institution of Oceanography of the University of California, has been named at the recent Executive Committee meeting as the Twenty-First William Bowie Medalist in recognition of his outstanding work in the theoretical aspects of geophysics and especially in the field of magnetohydrodynamics. The award will be made at the time of the Fortieth Annual Meeting of the AGU in Washington next May.

PACIFIC SOUTHWEST REGIONAL MEETING AT STANFORD, February 5–6, 1959—Plans for this meeting are now well along. Interested persons should get into touch with the Chairman of the Regional Committee, Vito A. Vanoni (California Institute of Technology, Pasadena 4, California), or with Joseph B. Franzini (Civil Engineering Department, Stanford University, Stanford, California), Chairman of the Program Committee.

FORTIETH ANNUAL MEETING TO BE HELD IN WASHINGTON, D. C., May 4–7, 1959—Your attention is invited to the extended announcement concerning this meeting on pages 993–994 of the October issue of the *Transactions*. Note that titles and abstracts of papers for the programs should be sent in as soon as possible to the appropriate persons and that in general the closing date is February 20, 1959, except for Meteorology for which the closing date is January 20, 1959.

Abstracts must be informative and concise, and not more than 150 words (see Suggestions to Authors in the *Transactions* of April 1957, p. 285, for ideas regarding abstracts).

Standard-size slide projectors (3¼ × 4 inches) will normally be available at the meeting, but other facilities will be provided only if especially requested well in advance. Persons inexperienced in the proper preparation of figures and tables for the making of slides should write to the AGU office requesting information on this. One general rule, however, is to avoid crowding and attempting to show too much on one slide. More than two or three curves on one slide tend to be confusing. Large-sized lettering is essential.

An advanced copy of the paper is requested for use by science writers and the press. Please send in by April 15, 1959. It is discouraging to have to tell a reporter inquiring about a certain paper, "That one hasn't come in."

In case the paper is being submitted for publication in the *Journal of Geophysical Research*, complete manuscripts, double-spaced, in triplicate, with figures and tables should be sent to Dr. James A. Peoples, Jr. (Department of Geology, University of Kansas, Lawrence, Kansas) noting that the paper is to be presented at the combing meeting.

The Section on Meteorology is to meet jointly with the American Meteorological Society. Commander Max A. Eaton (CNO (Op-583), Navy Department, Washington 25, D. C.) is Chairman for the joint program and material relating to the program should be sent directly to him. On this committee also are: F. W. Burnett, H. A. Bedient, A. W. Bostick, and H. V. Goodyear. The meeting in Meteorology will extend to May 7. Contributions in the following areas will be welcomed: cloud physics, synoptic meteorology, recent developments in forecasting and practice including utilization of numerical products, and meteorological instrumentation.

Block bookings have been made at three hotels as follows:

Roger Smith Hotel, Pennsylvania Ave. at 18th St., N.W.
Willard Hotel, Pennsylvania Ave. at 14th St., N.W.
Raleigh Hotel, Pennsylvania Ave. at 12th St., N.W.

Make your room reservation early directly with the hotel of your choice, citing the AGU block booking if you write to one of the three hotels noted.

PLANS FOR THE TWELFTH GENERAL ASSEMBLY OF IUGG—As previously announced, the Twelfth General Assembly of the International Union of Geodesy and Geophysics will be held in Helsinki, Finland, July 25–August 9, 1960. The following Committee has been designated by Finland's National Committee for Geodesy and Geophysics: President, W. A. Heiskanen; Vice President, Vilho Väisälä; Secretaries, Pentti Kalaja and T. J. Kukkamäki. Other members are R. A. Hirvonen (for the Association of Geodesy), Eijo Vesanen (for the Association of Seismology and Physics of the Earth's Interior), Matti Franssila (for the Association of Meteorology and Atmospheric Physics), Christian Sucksdorff (for the Association of Geomagnetism and Aeronomy), Ilmo Hela (for the Association of Physical Oceanography), Allan Sirén (for the Association of Scientific Hydrology), and Vladi Marmo (for the Association of Volcanology).

While citizens of the United States should make known their plans to attend and for participation through the U. S. National Committee (that is, the American Geophysical Union), other questions may be addressed to Secretary Pentti Kalaja, Finnish Geodetic Institute, Itämerenk 51, Helsinki, Finland.

PLANS FOR THE ENGLISH EDITION OF *Izvestiia*, GEOPHYSICS SERIES—*Bulletin* (*Izvestiia*), *Geophysics Series*, of the Academy of Sciencies, USSR, will be published in an English edition directly by the AGU for the calendar year 1959, according to present plans. Subscriptions ($25.00 for the 12 numbers to be issued during 1958) with payment should be sent direct to the American Geophysical Union. *Izvestiia* for 1957 is being produced by Pergamon Press under arrangements with the American Geophysical Union. Subscriptions for that year and purchases of back numbers for 1957 should still be sent to the Pergamon Press, 122 East 55th Street, New York 22, New York.

NATIONAL ACADEMY OF SCIENCES

Number 17 • November 1958

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Status of Geomagnetism Program

The following material is based primarily on a report to the US National Committee for the IGY by Elliot B. Roberts, Chief, Division of Geophysics, US Coast and Geodetic Survey, and Vice-Chairman, USNC-IGY Technical Panel on Geomagnetism.

The major portion of the earth's magnetic field is thought to be generated by electric currents within the earth. The remaining portion, about 5% of the field, is generated externally, it is believed, by great, globe-girdling systems of electric currents in the charged, or ionized, regions of the upper atmosphere. The earth-generated part of the field is relatively stable, undergoing slow, "secular" changes measured in years, tens of years, or even centuries. The externally-generated part of the field is characterized by rapid, or transient, fluctuations measured in days, hours, minutes, and seconds. It is with these transient fluctuations that the IGY Geomagnetic Program is mainly concerned.

Daily variations in the magnetic field are believed to be tidal (solar and lunar) in origin. Other rapid fluctuations and disturbances may result from the entry into the earth's upper atmosphere of (1) energetic ionizing radiations, and (2) high-velocity, electrically-neutral streams of corpuscles. Both the radiations and the corpuscles originate in explosive activity on the sun.

The magnetic-field vector (magnitude and direction) at any point is measured in terms of various elements or components. These include the magnetic intensity in the vertical and horizontal planes, dip (inclination of the magnetic vector with respect to the horizontal), and declination (the angle between the magnetic vector and the geographic meridian).

Continuous recording of the magnetic field components is accomplished with instruments called magnetometers or magnetographs. Absolute calibration must be applied to these instruments periodically with specially-designed magnetometers. At stations where observations are made over many years, permitting study of the secular changes, observatory-type instruments are employed. These are magnetometers characterized by low, uniform base-line drift and stable response. At stations established for short periods, where recording of magnetic-field variations and storm responses is of major interest, small portable magnetometers called variometers or variographs are used. Absolute calibrations are also applied to variometers, but in general the records are more useful for study of transient rather than secular changes.

The several components of the magnetic field have for years been measured and recorded by instruments installed at magnetic observatories in many parts of the world. These have helped form a picture of the overall magnetic field. During the IGY, however, networks of stations have been established in regions of special interest. Examination of the differences between records obtained at the stations reveals information on the behavior, location, and extent of the electric currents circulating in the upper atmosphere.

The objective of the geomagnetism program, broadly speaking, is to record synoptically the variations in the earth's magnetic field. The frequency band primarily under study ranges from about 50 cycles/sec to one cycle/yr. Geographic areas of greatest interest are the polar regions, including the auroral zones, and the rather narrow band along the magnetic equator. Figure 1 shows the locations of IGY geomagnetic stations in equatorial and middle latitudes as well as some in high latitudes (see *Bulletin No. 3* for map showing all polar stations).

Polar Regions

Records obtained at the magnetic observatories at the Little America, Byrd, Wilkes, and South Pole IGY Stations, Antarctica, furnish material for the study of magnetic storm conditions as a world-wide phenomenon—allowing comparison with records obtained in the equatorial and north polar regions.

The variometer on IGY Drifting Station A, in the Arctic Ocean ice pack about 300 mi from the North Pole, supplies information on general magnetic activity well within the auroral zone. Rotation, tilt, and drift of the station make necessary elaborate computations to reduce the records to standard components. Therefore, no routine reductions are contemplated.

Continental US

Records received from the east-west network of variometer stations in the United States are available for study of the effects of mass-transport of ionized gases or of other meteorological relations. At present, processing of the records consists only of tabulating mean hourly values.

South American Network

Near the magnetic equator, the daily variation in the horizontal component of the earth's magnetic field is unusually large. This abnormality is exceptionally well exhibited at Huancayo, Peru, where a permanent magnetic observatory is located very close to the magnetic equator.

In 1949, observations were made at fourteen locations along the west coast of South America, from geographic latitude 3.4° N to 16.2° S, to study this variation. These observations showed a steep decrease in the amplitude of the daily fluctuations of the horizontal component with distance north and south of the equator. This indicated the existence of a narrow band of concentrated electric current flowing eastward in the upper atmosphere during midday. This current—the equatorial "electrojet"—is superposed on the more diffuse current distribution that accounts for the normal, quiet-day magnetic variations.

To determine whether magnetic field variations other than the daily variation also show electrojet effects, four stations equipped with Askania variographs were established for the IGY on the west coast of Peru by the Department of Terrestrial Magnetism, Carnegie Institution of Washington, in cooperation with the Instituto Geofisico de Huancayo. They are located at Talara, Chiclayo, Chimbote, and Yauca, ranging from geographic latitude 4° N to 15° S. Magnetographs at the Instituto Geofisico de Huancayo (12° S) provide data at a fifth location and a magnetograph recently installed at the University of Arequipa (17° S) will provide data at a sixth.

To locate the latitudinal limits of electrojet effects on the daily magnetic variation, and to determine strategic locations for the four Askania variograph stations mentioned above, records were obtained at 16 more-or-less uniformly spaced locations between the geographic equator and 22° S in the spring of 1957. Two or three complete daily records were secured at each station.

The maximum daily variation of the

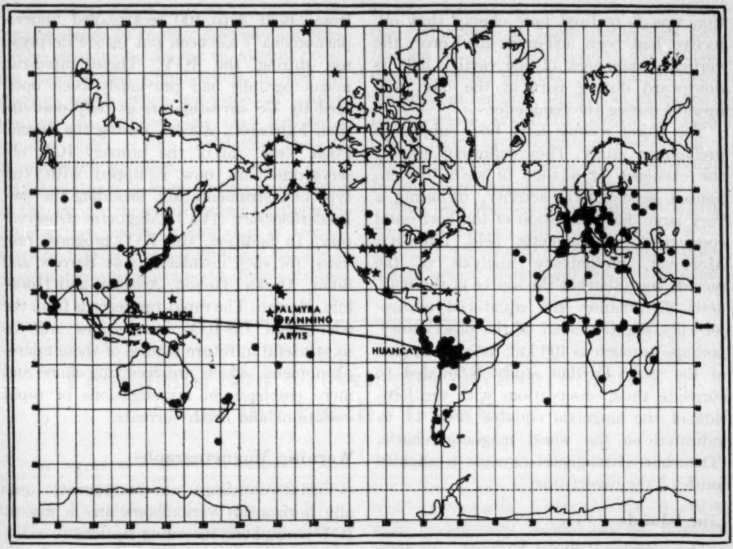

Fig. 1. *IGY Geomagnetic Stations. Stars: US Stations. Dots: Stations of other countries. Circled Stars: Cooperative Stations. Heavy solid line represents approximate position of magnetic equator.*

horizontal component was found to occur within 1° of latitude of Huancayo (12° S). This is in accord with results from the 1949 survey. It is also confirmed by the fact that the daily variation of the vertical component of the earth's magnetic field, obtained during the 1957 survey, changes sign at a latitude within 1° of Huancayo. A maximum daily variation in the vertical component occurred at about 16° S, and another maximum, with opposite sign, occurred near 8° or 9° S.

The north-south distance of 500 mi between these extremes provides a rough estimate of the width of the electrojet band. The difference with latitude of the daily variation of the vertical component indicates the importance of the return currents, which must flow westward, to the north and south of the eastward-flowing electrojet.

To estimate reliably the height and width of the electrojet, the electric current system of the electrojet field must first be derived. Before this derivation can be accomplished, the normal, quiet-day solar variation, estimated from data obtained at locations free from the influence of the electrojet, must be subtracted. Such height and width estimates have not yet been completed.

A preliminary examination of records indicates that many of the vertical-component fluctuations related to solar disturbances are greatest at the same latitudes where the largest quiet-day solar tidal variation in this component was observed. The sign of the fluctuations is opposite at these two latitudes, indicating electrojet effects.

Pacific

The site for the Koror Observatory, in the Palau Islands, was chosen with the intention of establishing a recording station as near as possible to the magnetic equator. Not until the observatory was actually in operation was it realized how closely that objective had been achieved: at Koror, the vertical component of the earth's field is downward during part of the day, and upward during the remainder.

The Koror records have been subject to preliminary study. They definitely support the existence of a zone of markedly enhanced geomagnetic activity, including a very large daily variation of the horizontal component of magnetic field intensity. Moreover, preliminary analysis of the records suggests that the source of the magnetic disturbance—the equatorial electrojet—lies slightly north of the observatory, perhaps as much as 100 km, for at least part of the year. Further study is needed to correlate these observations with the location of the magnetic equator (Fig. 1), as indicated on the world magnetic charts. (The charted magnetic equator is slightly south of the observatory.)

Line Islands

The Jarvis-Palmyra-Fanning project, operated by Scripps Institution of Oceanography with instruments supplied by the US Coast and Geodetic Survey, began operation very shortly after the formal commencement of the IGY.

Records from the three stations were shipped to the C&GS late in May 1958 for delivery to World Data Center A. Although there has been no opportunity to examine them critically, a preliminary inspection shows that the records tend to support observations made elsewhere of a concentration of electrojet effects in the vicinity of the magnetic equator. Such effects are indicated by the increased daily variation and by disturbance effects evident in the Jarvis records as compared with those from the more distant members of the group.

Rapid-Run Records

A type of instrumentation badly needed at US Magnetic Observatories for many years—instrumentation for recording rapid fluctuations of the earth's field in the range from about 4 to 100 secs (called "microphenomena") has been put into widespread use during the IGY. These rapid-run magnetographs had previously been operated by US investigators at only one station, Fairbanks, Alaska, during the Second Polar Year. All of the primary IGY observatories are now equipped with this type of instrumentation, including the new Fredericksburg (Va.) Magnetic Observatory. In addition, the IGY program provided for such installations at Barrow and Sitka, Alaska, Tucson, Arizona, and Honolulu, Hawaii. The rapid-run records from the widespread US-IGY installations will be most useful in future studies of these microphenomena, which are receiving more and more emphasis in investigations of rapid variations and earth currents.

Warning Magnetographs

Visible-recording, one-component (usually horizontal) variometers are in use at IGY ionospheric recording stations to assist in correlating ionospheric observations with the general level of magnetic activity. The records will not be systematically archived in the World Data Center.

Sub-Audio Project

The sub-audio frequency project was set up to provide a description, using magnetic tape recordings, of geomagnetic fluctuations in the frequency range of 1 to 50 cycles/sec.

The program involves investigation of the nature of sub-audio frequency signals which precede magnetic disturbances in the auroral zone by about a day. These signals may be confused with fluctuations originating in thunderstorm activity at lower latitudes. Hence, careful analysis is necessary. The most conclusive evidence will come from statistical analysis of the signal level as a function of frequency and time. Differences in signal levels between the vertical and horizontal components of the earth's field will also aid in this differentiation. Preliminary examination of the visual record of the overall signal level, at the time of recording, tends to confirm previous findings.

The records also appear to confirm previous reports that signal levels in this frequency range, when recorded at appropriately situated stations, can furnish a running index of the world-wide level of thunderstorm activity.

Observations of some of the wave forms of the signals show interesting phenomena. Among these is the appearance of oscillations or regular micro-pulsations. Signals of varying frequency also occur. Some of them at first decrease in frequency, resembling the "whistlers" of audio frequencies (see *Bulletin No. 6*). Then, however, they sometimes increase; whistler propagation could not account for this. Analysis of these wave forms—which, at such frequencies, probably result from hydromagnetic phenomena—should provide new data on the sub-audio frequency geomagnetic fluctuations.

Five field stations participate in the program—at Ramey Air Force Base, Puerto Rico; Ft. Devens, Mass.; Mt. Evans, Colorado; College, Alaska; and Thule, Greenland.

Pendulum and Gravimeter Measurements of the Earth's Gravity

This report is based upon material furnished by George P. Woollard, Department of Geology, University of Wisconsin.

The mass of the earth exerts an attractive force—gravity—on all bodies on the earth. However, because the earth is not a perfect sphere, because its mass is not uniformly distributed, and because the centrifugal force resulting from its rotation varies with latitude, gravity is not the same all over the earth. Measurement of the differences in gravity from place to place therefore reveals much information about the physical characteristics of the earth. Such measurements are especially important in studies of the true shape of the earth and the thickness and mass of its crust; in location of underground ore bodies and undersea mountains; and in accurately determining elevations and distances on the earth's surface.

The major aims of the IGY Gravity Program are to expand existing gravity networks in an effort to achieve as complete global coverage as possible, and to increase the reliability of gravity measurements. In the US program, scientists of the University of Wisconsin, under the direction of George P. Woollard, are making gravity determinations throughout the world using pendulums and gravimeters. Although less sensitive than gravimeters, pendulums can measure reliably changes in the gravity field of the earth. Hence, they are being used to establish a number of accurate key points to serve as linkages between the gravity networks of many countries and as a standard for calibrating the more sensitive gravimeters. Similar key points which existed prior to the IGY are being recalibrated. Within this framework, gravimeters are able to make highly sensitive measurements of the variations in gravity from one point to another.

A. PENDULUM PROGRAM

The IGY pendulum program is a continuation of one that has been under way at the University of Wisconsin since 1951. Early measurements revealed systematic and random errors in accepted gravity base values. These errors were too large to permit effective integration of the world's gravity data into a unified whole having an overall accuracy approaching the desired value of 1 milligal. (One milligal, or mgal,

equals $1/1000$ gal, which represents an acceleration of 1 cm/sec.^{2}) Actually, apparent errors of over 20 mgals were discovered. The Gulf compound quartz pendulum apparatus was chosen to establish a series of world standardization measurements as it appears to hold the greatest promise for obtaining accurate values of gravity throughout the world.

Description of Apparatus

The Gulf pendulums are designed to minimize knife-edge wear effects at the point of suspension, and the pendulum case is ionized with a radioactive salt to dissipate electrostatic charges built up on the moving pendulums. The pendulums are operated at constant temperature and are kept sealed in a dry atmosphere. The use of two pendulums swinging 180° out of phase on a common support minimizes sway in the support. Timing is done with a crystal-regulated chronometer periodically checked against WWV radio time signals. Recording was first done photographically, but now the period is read directly from an electronic digital recorder.

Observation Procedure

An observation consists of four independent pendulum measurements of one hour's duration each. The four measurements are made to eliminate errors that result because the pendulum knife edge is positioned slightly differently on the bearing flats during each measurement. When variations between independent swings are greater than ±0.2 mgal, observations are continued until four agree within this arbitrary limit. The mean value for all swings is adopted as the period for the site.

To guard against error, two precautions are now being taken that were not followed earlier. One is to repeat in reverse order any series of observations. For example, the series Panama, Quito, Lima, La Paz, Santiago would be repeated from Santiago back to Panama. The other is to use a geodetic gravimeter in conjunction with the pendulum observations. Thus, if there are any jumps owing to knife-edge wear, or to any other cause, there is a double check to indicate where and when trouble occurred and how much of an error was introduced. Since this procedure was adopted, with the beginning of the IGY program, there have been no problems concerning values. This does not apply to earlier measurements, some of which were doubtful and required repeat observations.

Accuracy of Values

Studies involving three different sets of pendulums have been conducted, and while a single set of pendulums is inherently consistent to ±0.2 mgal, one set may differ from another by as much as 1.0 and occasionally 1.5 mgal on an interval measurement.

In addition, comparative measurements have been made against the magnetically compensated compound Invar pendulum of Cambridge University, England, and the magnetically compensated single Invar pendulum apparatus of the US Coast and Geodetic Survey. Such comparisons show no systematic differences; overall agreement within 1 mgal was obtained between Alaska and Mexico (see Table 1).

Another independent evaluation of the pendulum results is furnished by comparative measurements with carefully calibrated, high-range, geodetic-type gravimeters having a reading accuracy of 0.1 mgal. Here, the average agreement is found to be about ±0.5 mgal (see Table 2).

On the basis of all of these comparative measurements, it appears that an accuracy of about 0.3 to 0.5 mgal is being obtained with the Gulf pendulums.

Program of Observations

Prior to the IGY, one series of pendulum measurements from Mexico City to Fairbanks, Alaska, had been completed, covering a range of approximately 4800 mgals. This series was adopted as a standard for determining the operating characteristics and calibration of high-range geodetic gravimeters used by the University of Wisconsin for global gravimeter measurements. To strengthen these standardization measurements, the Dominion Observatory of Canada, using the Cambridge pendulums, and the USC&GS reoccupied most of the University of Wisconsin sites. On the basis of the agreement obtained, it was decided to extend the pendulum program and establish another, comparable standardization range for other parts of the world. At the same time, this would serve as a control net of bases for integrating gravity data from all sources into a unified system. This second series of Gulf pendulum bases was established just prior to the IGY. It extends from Oslo, Norway, to Cape Town, South Africa. At most of the sites occupied, observations have also been made with the Cambridge pendulums.

A problem in gravity work is the use of several different gravity calibration standards in different parts of the world. These differ by as much as 12 mgals per 1000 mgals of change in gravity. As this situation leads to major discrepancies that would hamper attempts to integrate world data, it was decided that additional Gulf and Cambridge pendulum measurements were desirable. These were included in the IGY Program.

Results

The program to date has resulted in a new series of Gulf pendulum measurements which extends the North America standardization range northward to Pt. Barrow, Alaska, on the Arctic Ocean, and southward through Panama to Punta Arenas, Chile, at the southern tip of South America. Figure 2 shows the geographic distribution of Gulf pendulum sites. In the Pacific Ocean area, measurements have been established

Note: W10F and 147 are two different Worden gravimeters.

along another north-south line—from the island of Hokkaido, Japan, southward through Australia and New Zealand to McMurdo Sound, Antarctica. Another meridional series of measurements is planned from northern Greenland southward to southern Argentina, and it is hoped to make some supplementary measurements in western Europe and Africa to round out the existing networks in these areas.

In addition, complementary measurements with the Cambridge pendulums have been made in Europe and Africa by B. C. Browne of Cambridge University, and measurements with these instruments are now in progress in South America.

B. GRAVIMETER PROGRAM

About ten years ago the first practical geodetic-type gravimeter was developed by S. P. Worden of Houston, Texas. This instrument has revolutionized the use of gravity measurements, not only for geodetic studies but also for many regional geophysical studies related to earth structure and geology. It overcame all of the major problems previously restricting long-range gravity connections. The instrument was small, light, rugged enough for field use, had a self-contained power source consisting of small dry-cell batteries, and had a reliable reading time of less than 5 min.

For the first time it was feasible to use commercial air transport for gravity measurements. Without special facilities and arrangements, a gravity reading could be made during the few minutes a plane was on the ground for a routine stop. A closed traverse of as much as 1000 mi could be completed within 12 to 14 hrs and a series of observations extending completely around the world in less than one week.

Although the Worden gravimeter is compensated for changes in temperature, it has an appreciable "drift" rate resulting from slow relaxation of the spring over a period

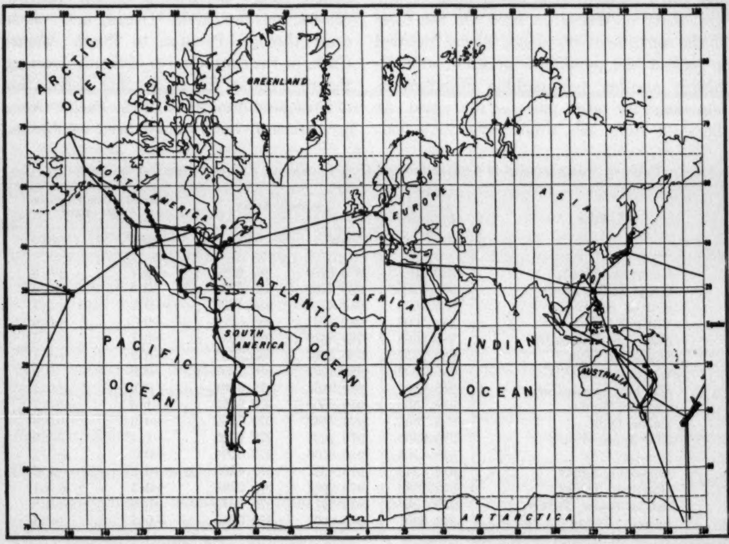

Fig. 2. *World Network of Pendulum Gravity Stations*

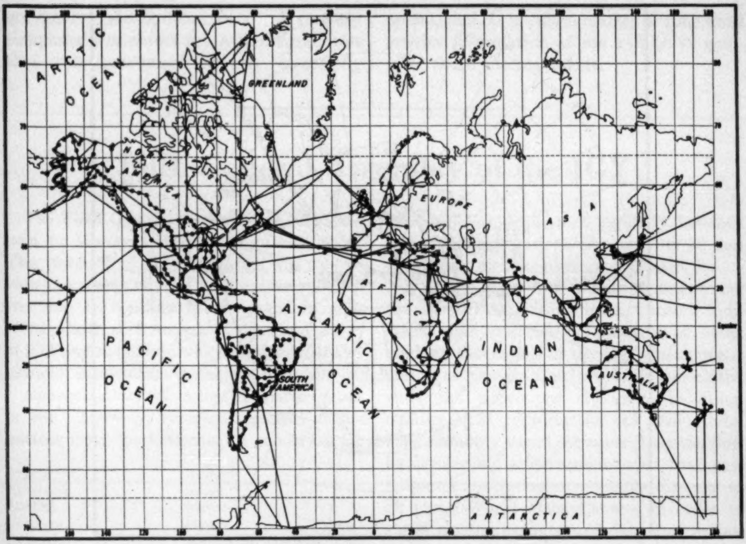

FIG. 3. *World Network of Gravimeter Stations*

of time. However, the speed with which the instrument can be used minimizes this drift effect. On the average, results reliable to 0.3 mgal can be obtained almost anywhere to which air transportation is readily available. The biggest problem in its use is that of calibration. (It was to resolve this problem that the program of gravity standardization measurements using Gulf pendulums was set up.)

How well these problems have been resolved is indicated by the comparison between pendulum gravity values and those for two Worden gravimeters having markedly different scale constants, sensitivity, and range values (Table 2).

Objectives of Program

The general objectives of the IGY gravimeter program, as in the pre-IGY period are: (1) to evaluate the accuracy of the various national gravity bases; (2) to integrate the national gravity bases into a unified network; (3) to extend and strengthen the international network of bases; and (4) to build up auxiliary gravity coverage on a regional basis in areas not likely to be investigated in the forseeable future.

Figure 3 shows the locations of the principal gravimeter bases, most of them at airports, throughout the world. Although a total of over 3000 bases have been established in 85 countries, large gaps still exist.

The IGY gravimeter program also includes establishment of base gravity values in Antarctica; traverse measurements in Antarctica; ice floe observations in the Arctic Ocean, with periodic ties to these stations from mainland bases; checking of key stations in the primary world network using the new, precise, "driftless," constant-temperature, LaCoste geodetic gravimeter; and expansion of the overall world net of gravity bases.

Fig. 4. *Gravity Stations and Lines Along Which US and British Gravity Measurements Have Been Made in Antarctica. Solid lines represent oversnow traverses; dashed lines represent ship or air routes.*

Antarctic Measurements

Figure 4 shows the locations of IGY gravity bases in Antarctica and routes along which gravity measurements were taken. The route of the British Commonwealth Trans-Antarctic traverse is also indicated since the gravity measurements on this traverse were made on a cooperative basis with an instrument provided by the University of Wisconsin.

Preliminary gravity values for the various Antarctic bases are listed in Table 3. Anomaly values (free-air) for the Byrd Station traverses average ±50 mgals from zero. These small anomalies suggest isostatic equilibrium, in which there is neither an excess nor a deficiency of crustal mass, thus implying crustal stability. The minor fluctuations, however, suggest considerable variation in the thickness of ice, the underlying rock types, or both. (The manner in which traverse gravity measurements have served to supplement the seismic measurements in determining the thickness of the ice cap is discussed in *Bulletin No. 13*.)

Marine Measurements

One of the more significant phases of the US-IGY Gravity Program is the work being done by the Lamont Geological Laboratory in developing a workable shipboard adaptation of the Graf motion-compensated gravimeter (see *Bulletin No. 8*). A recently completed run across the Atlantic indicates that this instrument is now essentially operational. It is only a matter of time until gravity information at sea will be as complete as on the continents.

Fifth General Assembly of the IGY

The Fifth General Assembly of IGY was held in Moscow, July 30–August 9, 1958. The purpose of the Assembly was to review the status of IGY as it approached its end and to consider future needs in geophysics both with respect to the termination of IGY and to fields in which additional international cooperation appeared desirable.

Approximately 365 scientists participated in the Assembly, representing IGY committees from the following 35 countries:

Argentina
Australia
Austria
Belgium
Bulgaria
Burma
Canada
Chile
Czechoslovakia
Denmark
Finland
France
German Democratic Republic
German Federal Republic
Ghana
Hungary
India
Iran
Ireland
Israel
Italy
Japan
Mongolian Peoples Republic
Netherlands
New Zealand
Norway
Poland
Rumania
Sweden
Union of South Africa
Union of Soviet Socialist Republics
United Kingdom
United States
Viet Nam Democratic Republic
Yugoslavia

The Assembly was called by the Special Committee for the IGY (CSAGI). As at previous general assemblies, the meeting of CSAGI was characterized by working groups in the various IGY fields: world data centers, world days, meteorology, geomagnetism, aurora and airglow, ionospheric physics, solar activity, cosmic rays, glaciology, oceanography, rockets and satellites, seismology, gravity measurements, nuclear radiation, and publications. The working groups, composed of scientists from the various delegations, met regularly between the opening plenary session on July 30 and the closing plenary session on August 9.

A review of the flow of data to and among the three IGY World Data Centers indicated that satisfactory progress is being made in this aspect of the IGY if account is taken of the routine problems associated with the collection, checking, handling, mailing, and reproduction of basic data. The Assembly urged, however, that the flow be accelerated and recommended that participants make copies available directly to all three World Data Centers in order to speed up the exchange of data and reduce the reproduction burden on the Data Centers. The Assembly requested that, in addition to the raw data, the World Data Centers also collect reprints of published results of IGY programs, and, in view of the value to scientists of these comprehensive collections of data, that the Centers continue in operation for as long as possible.

The single area in which completely satisfactory agreement was not achieved related to rocket and satellite data. With regard to scientific data from rocket and satellite experiments, alternate proposals were made. One advocated that preliminary data be supplied on a routine basis to the World Data Centers in advance of final publication, the other that only final published papers be supplied routinely, with preliminary data furnished only on specific request. A second point of difference was whether size, weight, and other information should be provided on all objects in orbit, including carrier rockets and nose cones, or only on instrumented satellites. Finally, a question arose as to whether precise orbital data should be supplied or only approximate direction angles for each observing station. The CSAGI has proposed a special committee to consider these three topics, and it is hoped that a satisfactory resolution may be achieved. This would then provide detailed agreement in the rocket and satellite area equivalent to that in the other IGY disciplines.

The Assembly recommended that a World Magnetic Survey be undertaken during the coming period of minimum solar activity. IGY studies provide data during the peak of the sunspot cycle, when the magnetic field undergoes rapid variations. The World Magnetic Survey, however, would provide data on the slow changes of the magnetic field and provide an up-to-date magnetic map. Such surveys are best conducted in magnetically quiet periods, the next of which takes place some four or five years from now. This recommendation will be considered by the International Council of Scientific Unions (ICSU) and by the various members of ICSU, such as our own National Academy of Sciences.

The question of prolonging the IGY for another year was raised by the USSR-IGY Committee. It was decided that the period of intensified geophysical-research effort of the IGY should terminate as planned. However, it was proposed that the coming year be designated "International Geophysical Cooperation-1959" (IGC-1959) and that observational and data-collection activities continue along the general plan of IGY "as far as practicable and at such level and in such fields as may be determined by each participating committee." The resolution has been endorsed by ICSU and its adhering bodies; this will have the following results:

First, it will provide a means for continued interchange of data among countries, and it is planned that data contributed from geophysical research during 1959 would be deposited in the IGY World Data Centers. Second, it will provide a transition period between the present IGY program and subsequent scientific programs in which clear need for further international cooperation arises. The Antarctic and oceanography programs are examples of the latter. ICSU has established special committees for these programs.

The Special Committee on Antarctic Research has already planned a 1959 program for continued efforts by those countries which have been active in the Antarctic during the IGY. A similar committee has been established for oceanography, although the plans for this committee are longer-range. In addition, ICSU will soon consider the establishment of appropriate committees in several other areas, including (i) rocket and satellite research, (ii) solar patrols and alerts, and, perhaps, (iii) the proposed World Magnetic Survey.

Agreement was reached on the publication of processed IGY data and results. A series of volumes, to be published in the *IGY Annals*, will be prepared under the direction of a specialist in each field (the World Reporter). Although complete publication will take several years, the program will afford many advantages: First, economy in publication will be realized through this cooperative, international plan. Second, wide distribution of the IGY results will be possible through a single medium. Third, the long-range burden on World Data Centers should be appreciably reduced by the availability of these volumes of processed data, reports of activities, and research papers.

During the Assembly, a number of special symposia were held. A total of some 200 scientific papers, distributed among the following disciplines, were presented:

Aurora and airglow; cosmic rays; geomagnetism, in a symposium on geomagnetic and ionospheric disturbances; glaciology; ionospheric physics, in symposia on meteors and on the ionosphere; meteorology, in symposia on numerical forecasting, noctilucent clouds, Antarctic meteorology, and nuclear radiation; oceanography; seismology; rockets and satellites, in symposia on satellite orbits, satellite tracking, atmospheric structure (electrical), atmospheric structure (non-electrical), satellite radio observation, extraterrestrial radiation observations, and miscellaneous; and solar activity.

In addition, at all discipline working-group meetings, reports were presented by participating committees on their programs.

Summer Activities—Drifting Station Alpha

This report is based primarily on material supplied by Norbert Untersteiner, University of Washington, and T. Saunders English, University of Alaska.

The scientific program at Drifting Station Alpha, one of the two US-IGY stations established on the drifting ice of the Arctic Ocean, has continued almost without interruption despite severe logistic problems.

During the latter part of April, a part of the floe on which the station was built broke off and newly-formed pressure ridges advanced into the camp area. All but ten persons, including both scientific and supporting military personnel—just enough to keep the program serviced—were evacuated. On May 2, the Alaskan Air Command, 11th Air Division, which is responsible for station logistics, decided to move the camp to an adjacent floe about one mile away. The personnel who had been evacuated were returned and removal operations begun.

The task of moving was difficult because of the roughness of the ice surface and the need to jack up all structures in order to place runners beneath them. Moreover, it was necessary to dig power cable out of the ice in order to salvage as much of it as possible.

Because power cable had to be salvaged, spliced, and installed before rawinsonde observations could be made at the new site, two such readings were missed. The IGY seismic, gravity, oceanography, and magnetic programs of Station Alpha, however, continued on schedule. By May 24 the entire camp—consisting of 21 buildings—had been moved and a runway constructed at the new location.

On June 10, two leads (long, narrow water passages in the pack ice) formed across the new runway. Construction of a replacement runway was hampered by the beginning of the melt season, but by continuous draining through core holes it was possible to ready a strip for a C-54 aircraft on June 22. Shortly thereafter, a crack also formed in this runway. From then until late September, when the first landing of the winter season was made, the station was supplied by airdrop.

Biology

Though not among the disciplines for special IGY study, biological studies were emphasized in the summer program. T. Saunders English of the University of Alaska has been gathering data for an environmental study of the marine life under the floating ice. In addition to instrumental observations of the ice-water environment, the program includes direct observations underneath the ice in "frogman" gear with self-contained breathing equipment.

The amount of light energy in the sea is almost beyond doubt the limiting factor for the photosynthetic process, which is the basis of life in the sea. In the Arctic Ocean, a large portion of the sunlight is blocked off by the floating ice covering 90–95% of the sea surface. Many hypotheses have been put forth about the extent and variation of solar radiation passing through the ice cover. Direct observation of the transmitted radiation, by an undersea diver carrying suitable instruments, seems an excellent way to obtain the data necessary to evaluate these hypotheses. Three divers are using submarine photometers with filters to estimate the amount of light available to the plant life growing under the ice.

The underwater program also includes direct observation and sampling of the marine life on the underside of the ice. Previous work has shown that there is a considerable population of diatoms (microscopic plants with siliceous shells) attached to the underside of the ice; that many crustaceans appear to graze on the diatoms; and that seal feed on the crustaceans. Standard sampling equipment fails to give an adequate estimate of the populations involved in this food chain and gives no insight into natural conditions. Direct inspection by an observer under the ice permits description of the plants and animals on the undersurface of the ice, determination of their relationships to one another, and effective sampling for estimates of the populations involved.

It is hoped that these observations will clarify the relationship of this food chain to the unexpectedly large animal population found in high-latitude Arctic waters.

The phytoplankton (plant plankton) studies begun in 1957 were continued and expanded. Standing-crop samples and large-volume samples were taken for identification of plankton. (Standing-crop samples give a quantitative measure of the numbers and kinds of plants; large-volume samples provide a non-quantitative, overall picture of the marine population.) Preliminary analyses of the standing-crop samples showed the expected increase in productivity for the sunny summer months. Complete productivity studies, which can be only partially accomplished at Station Alpha, will include analyses of oxygen consumption and production, carbon-14 accumulation, and chlorophyll abundance. The data obtained will be analyzed to determine daily, seasonal, and depth variations in plankton productivity.

Samples of sea water for chemical analysis were taken at regular intervals. Preliminary analyses for chlorinity, oxygen, phosphates, silicates, nitrates, and nitrites were made at the station. Other samples will be returned to the mainland for more detailed analysis. The microstratification of the upper layers of the water was studied. A thermal probe was used to measure temperature, and the samples of water taken from specific levels were analyzed. The chemical studies and stratification studies should provide data describing the physical environment of the plankton and the nutrients available in the seawater.

In addition to the near-surface studies, horizontal plankton tows were made at various depths to collect foraminifera (microscopic, one-celled, hardshelled animals), and bottom trawls were taken. The bottom trawls have collected two kinds of echinoderms—brittle stars and sea cucumbers—as well as a number of rocks.

Sea-Ice Physics

The IGY sea-ice physics and glaciology investigations on Station Alpha (see *Bulletin No. 12*) were accelerated during the summer. Observations of ice accretion and ablation (loss, primarily by melting) were continued at the old site even after the camp was moved. (By September 1 the distance between the new and old sites had increased to two miles.) The 1958 melt season began two weeks earlier than in 1957 and lasted one month longer. Ablation during the 1958 melt season was found to be twice as great as in 1957, but less than accretion during the 1957–1958 winter. Thus, the total thickness of the floe increased during the year.

Ice Petrography: Core holes were drilled through the sea ice at regular intervals along lines crossing relatively undisturbed portions of the floe. The cores obtained are analyzed microscopically and chemically; this provides a three-dimensional picture of the fine structure and the salinity of the ice both along the sampling line and to the bottom of the floe. For selected cores, thin sections of ice from 10-cm intervals were prepared, examined microscopically, and photographed. It was possible to correlate the microscopic structure of the ice with its salt content and also to trace individual layers in the ice for horizontal distances of 10 to 20 m. The layer formed during the past winter, 50 to 70 cm thick, is particularly clear and has been observed in most cores.

Mechanics of Sea Ice: On May 14, Andrew Assur and Guenther Frankenstein, of the US Army Snow, Ice and Permafrost Research Establishment, began an intensive study of the strength of sea ice under natural conditions. They measured the tensile and compressive forces needed to break beams of ice cut from the floe; determined salinity and density; measured the electrical resistivity of sea ice; determined the elasticity of sea ice; measured the deformation of ice under load; and surveyed ice conditions in general.

Underwater Sound

Charles W. Senior of the Navy Hydrographic Office and E. P. Kelley of the Underwater Sound Laboratory arrived on June 21 to begin a study of long-range, underwater sound transmission between Station Alpha and Station Bravo, almost 400 mi to the south. The latter is on Fletcher's Ice Island, a large piece of shelf-ice thought to have broken off the Ellesmere Ice Shelf. Sound transmission tests were conducted at various depths. Measurements of vertical distribution of ocean temperature and salinity, which affect sound transmission, also were made.

IGY Bibliographic Notes

This is the fourth of a series of bibliographic notes on IGY programs and findings. The references are selected largely from an IGY bibliography under preparation in the Science and Technology Division of the Library of Congress.

IGY Bibliography

"An Interim Bibliography on the International Geophysical Year" has been published by the National Academy of Sciences.

This is the first of a series of bibliographies on the International Geophysical Year to be prepared by the Library of Congress as a joint project of the Library, the Academy, and the National Science Foundation. It is expected that it will be followed by a second interim volume in the spring of 1959 and later by a final complete bibliography listing all references on the IGY of scientific interest collected by the Library of Congress prior to July 1959.

The 64-page publication lists 704 references on the International Geophysical Year published between January 1951 and August 1958. The basis for selection of each entry has been the scientific value, the extent of coverage, historical interest, uniqueness, and to a lesser extent, availability. Titles in Russian, East European languages, and Japanese have been translated into English. The existence of complete translations and English summaries is noted where available.

The Interim Bibliography is priced at $1.00, postage prepaid. Orders should be addressed to the Publications Office, National Academy of Sciences, Washington 25, D. C.

NATIONAL ACADEMY OF SCIENCES

Number 18 • December 1958

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Program in Biological and Medical Sciences, 1958–1959

The Committee on Polar Research of the National Academy of Sciences and its Panel on Biological and Medical Sciences, in cooperation with the National Science Foundation, has prepared a broad program as part of the continuing US scientific research in Antarctic regions. The program, to be pursued primarily in the post-IGY period, is an outgrowth of the interest in life sciences that developed during the course of IGY studies in the physical sciences in this remote area. Australia, Great Britain, Argentina, and other nations are also supporting continuation of biological programs in the south polar regions. Of the twelve US scientists participating in this program, three will remain and continue their work during the austral winter.

At the US Naval Air Facility, on Ross Island in McMurdo Sound, a permanent laboratory will be installed by 1959 to support field studies in biology, medicine, and other life sciences in the coming summer season. In addition to a wide variety of equipment, biological supplies, and culture media, the laboratory will have a library of standard references, special texts, and the scientific reports of past Antarctic expeditions as well as current materials pertinent to Antarctic research.

Human Medicine

Medical studies of the incidence of respiratory infections, the isolation of the organisms responsible for such infections, and the development of new field techniques for their control are being carried out by a medical team supervised by William J. L. Sladen, Johns Hopkins University, Baltimore, Maryland. These studies are being made at the joint New Zealand-United States Hallett Station, at Wilkes Station, and at NAF, McMurdo. The medical team is using a temporary laboratory on board the USS *Staten Island* until the laboratory at NAF, McMurdo is completed. Robert M. Chanock, Respiratory Unit, National Institutes of Health, Bethesda, Maryland, will cooperate in phases of the work to be conducted in the United States. Rainer Goldsmith is conducting the laboratory investigations on board the *Staten Island*.

Ornithology

Ornithological work includes studies of the breeding biology of Antarctic birds, particularly of penguins, the south polar skua, and the giant petrel. The birds are also banded for study of their migration habits. These investigations are partly extensions of the research conducted by Carl Eklund while Station Scientific Leader at the US-IGY Wilkes Station during the 1957–58 period, and of studies initiated by Sladen during his period of Antarctic service with the Falkland Islands Dependencies Survey (UK) on the Palmer Peninsula.

At Wilkes Station, a year-long study of

the social and parental behavior of the Adélie penguin, and of its orientation mechanism in migration, is being undertaken. This research is conducted by Richard Lee Penney, graduate student at the University of Wisconsin, Madison, Wisconsin. Penney is one of the three Americans who will winter over at this station.

Penney is also collecting samples of egg white for C. G. Sibley, Cornell University, who is making a taxonomic study of avian proteins under a National Science Foundation grant.

Animal Parasitology

Parasitological studies of birds and mammals will be made, principally at the IGY Hallett and Wilkes Stations and at NAF, McMurdo. In addition to collections of internal parasites of seals and birds, Sladen and Goldsmith are making a special collection of birds' heads and necks. These will be returned to the United States for study by Gordon M. Clark, biologist and authority on mites inhabiting the respiratory passages of birds. He will study the specimens at the Patuxent (Md.) Research Refuge of the US Fish and Wildlife Service.

Entomology

In the field of entomology, an investigation of land invertebrates is being carried out by Madison E. Pryor, graduate student at the University of Tennessee, Knoxville, Tennessee. He will work at the biological laboratory at NAF, McMurdo. Pryor is one of two biologists who will winter over at McMurdo.

Botany

A special study of Antarctic mosses is being made during the austral summer by Elmer G. Worthley, Sr., Arctic Institute of North America, in the region of Ross Island, McMurdo Sound.

Marine Biology

Marine biology studies are being conducted by six investigators working partly from ships and partly from the laboratory at NAF, McMurdo. A study of the food cycle of marine fauna is being made at Hallett Station and at NAF, McMurdo. It will be continued, by invitation from the New Zealand Oceanographic Institute, aboard the New Zealand oceanographic research vessel HMNZS *Endeavour* during a cruise along the Antarctic convergence zone and in the Ross Sea. (The convergence zone is the region in which the cold waters of the Antarctic current sink beneath and mix with warmer waters of the West Wind Drift.) This work will be carried out by Richard G. Miller, of Long Beach State College, Long Beach, California. He will be assisted by John Resek, Jr., Costa Mesa, California.

Donald E. Wohlschlag, Chairman, Department of Biological Sciences, Stanford University, is studying the ecology of inshore marine invertebrates at NAF, McMurdo. John H. Dearborn, graduate student at Stanford, is assisting him. Dearborn will continue these studies at the biological laboratory at McMurdo during the winter.

Hugh H. DeWitt and James C. Tyler, also graduate students at Stanford University, are accompanying, respectively, the USS *Glacier* through the Ross Sea to McMurdo Sound, and the USS *Edisto* to IGY Ellsworth Station on the Weddell Sea. Under the direction of Wohlschlag, they are carrying out studies on the systematics, or classification, of Antarctic fishes and making other marine biological observations. Particular study is being made of the physiological properties of blood and of anatomical adaptations to feeding habits and habitat.

Tyler is also collecting sera from Antarctic fishes for the Serological Museum at Rutgers University.

Psychology and Psychiatry

An analysis of selection and performance data of wintering-over personnel, based on diary materials, psychiatric evaluations, and interviews, will be conducted by William M. Smith, graduate student at George Washington University, Washington, D. C. The purpose is to evaluate factors that may be useful in selecting scientific personnel for future work in isolated regions; to report on the performances of scientific personnel during their stay in the Antarctic; and to describe the group structure at the scientific stations and the roles played by the individual members of the various scientific parties.

IGY News From Other Countries

A. Progress of the United Kingdom Program

The following account is based on summary reports of the first twelve months of the United Kingdom IGY Program. The reports were presented by the British National Committee for the IGY to the Fifth General Assembly of the IGY, held in Moscow, July 30–August 9, 1958.

The United Kingdom Program, which includes all IGY disciplines, got under way promptly with the start of the IGY on July 1, 1957, and has proceeded according to plan. The activities of the first twelve months produced many significant results. Among them are the discovery of a southward-flowing countercurrent in the eastern Atlantic similar to the one found earlier beneath the Gulf Stream; correlations between auroral activity in the northern and southern hemispheres, and, in the Antarctic, between the aurora and geomagnetic and ionospheric activity; and observations of two distinct radio-wave-reflecting structures in the F layer of the Antarctic ionosphere.

In the Antarctic, the most extensive United Kingdom program is concentrated at the Royal Society IGY Station, at Halley Bay on the eastern side of the Weddell Sea. Here, the entire scientific program, comprising investigations in meteorology, geomagnetism, aurora, ionospheric physics, glaciology, and seismology, was functioning by June 20, 1957.

(Other United Kingdom Antarctic stations are maintained on the Palmer Peninsula and in the South Shetland and South Orkney Islands, near the northern end of the Peninsula. Shackleton Station, on the Filchner Ice Shelf, and South Ice Station, on the polar plateau between Shackleton and the South Pole, although established primarily as bases for the Commonwealth Trans-Antarctic Expedition, also supported programs of scientific investigation—in meteorology and glaciology, in particular.)

Meteorology

In addition to the standard meteorological program, British Ocean Weather Ships in the Atlantic are recording solar radiation. Ozone sounding equipment of the electrolytic-absorption type has been flown on balloons released at Halley Bay, at Malta, and in England, providing data on the vertical distribution of ozone to altitudes of about 20 km. A rapid rise in total atmospheric ozone was observed at Halley Bay in late October 1957; a similar increase occurred just one year earlier.

In the meteorology program at the Royal Society Station, standard surface measurements, including temperature, pressure, humidity, and wind speed and direction, are made continuously or at frequent, fixed intervals. The lowest temperature recorded since establishment of the station was −51°C (−60°F), in July 1957; the highest was 2°C (36°F), in January 1957. A wind speed of 77 knots, almost 90 mph, was recorded in June 1957.

Standard surface observations were made on the Commonwealth Trans-Antarctic Expedition and at Shackleton and South Ice Stations during most of 1957.

Glaciology

The glaciology program includes studies in the Antarctic and in glacier regions of tropical East Africa. An expedition by Sheffield University scientists to Mt. Kilimanjaro was completed in January 1958, and other expeditions to East African glaciers were included in the 1958 program. Field work has been completed on South Georgia Island in the South Atlantic, and glacier-regime studies and other observations have been made in the Falkland Islands. Glacier fluctuations relative to climate during the past 50 years were included in the South Georgia studies.

Royal Society Station: Glaciological investigations during the first twelve months at the Royal Society Station, which lies on a partly grounded ice shelf several hundred feet in thickness, were limited to studies of accumulation and ablation in the vicinity of the station, of temperature gradient within the ice, and of past variations in the net accumulation. Studies of related meteorological factors were made simultaneously. These included radiation balance, heat transfer and variation of temperature in the near-surface layers, and snowfall.

Snow accumulation was measured by use of stakes and in a small pit. Meteorological data served as a guide to the dating of wind crusts and snow deposits. These accumulation measurements were correlated with others made on sledge trips to points as far as 30 mi from the station. Annual accumulation back to 1943 averages 38 cm, with a large total range of 18 to 77 cm.

The report adds that "the detailed notes on the layers appear to provide useful evidence of the meteorological characteristics of each year, for example of the frequency of 'warm periods' in the winter. In several of the summers there is no indication that melting occurred."

Study of the general characteristics of the ice shelf and of the sources which feed it was made by air reconnaissance. The positions of ice-fall areas and crevasses gave some indication of the location and configuration of the coastline proper. The rate of movement of the shelf ice appears to be very slight, but definite.

Commonwealth Trans-Antarctic Expedition: Seismic soundings to determine the thickness of the ice sheet and the nature of the underlying materials were made at 30–70 mi intervals from South Ice Station to the Skelton Glacier. Ramsonde measurements were made frequently and the cores examined. At seismic stations, temperatures were measured at one-meter intervals, to a depth of 11 meters, in the ramsonde holes.

At South Ice, snow accumulation was measured and a study of the effects of the surface micro-climate on accumulation and ablation was made. A 50-ft-deep snow pit was dug for studies of ice-crystal orientation and snow strata. A 3-in bore hole drilled from the bottom of the pit extended these observations to a depth of 100 ft.

Oceanography

United Kingdom research vessels cooperated with vessels of the Woods Hole Oceanographic Institution in the discovery and investigation of a southwest-flowing countercurrent beneath the Gulf Stream (see *Bulletin Nos. 2* and *8*). Detailed measurements were also made, in collaboration with Woods Hole, of the temperature, salinity, oxygen, and other variables across the Atlantic at 24°, 32°, and 48°N latitude.

Cooperative investigations with Norwegian and French research vessels have revealed another countercurrent about 640 km (400 mi) west of Oporto and Lisbon, Portugal. It flows southeastward at speeds of 1.5 to 3 km (1 to 2 mi) per day below a depth of 1400 m (about 4600 ft). Other deep-water studies have been made in the Atlantic west of the English Channel; in the Straits of Gibraltar, Bab-el-Mandeb (between the Red Sea and the Gulf of Aden), and Hormuz (between the Persian Gulf and the Gulf of Oman); and by British weather ships.

In the Antarctic, gravimeter records for Shackleton Station show the rise and fall of the 1300-ft-thick Filchner Ice Shelf with the tide. The report states that "No other method of tidal observation at the head of the Weddell Sea was practical owing to the great depth of the sea (500 fathoms) at the edge of the ice shelf."

Geomagnetism

In the Antarctic, an effort is being made to measure the water currents and associated electrical currents in the Weddell Sea below the edge of the Filchner Ice Shelf. Thus far, the records have failed to show any geomagnetic effects related to such electrical currents.

Aurora

Significant results have been obtained in the aurora program at the Royal Society Station, where auroras were observed on all dark, clear nights. The report states that considerable auroral activity occurred north of the zenith, and there were many full coronas with centers usually 118° above the southern horizon. At times, auroras were seen within 10° of the northern horizon; this corresponds to overhead displays at a position roughly 29° from the geomagnetic pole, if it is assumed that the aurora is 100 km above the earth's surface.

"... the impression gained was that for flaming diffuse surfaces without any rayed structure the motion of the waves of luminosity was directed along the local geomagnetic meridian [rather than toward the magnetic zenith].... When rays were present the waves appeared to move towards the magnetic zenith but this is the effect to be expected when waves of excitation cut across the rays at an angle. It is concluded that in all cases the direction of motion was along the geomagnetic meridian but that the presence of a rayed structure produced a disturbance."

Comparison of auroral data with radio-echo data: The Royal Society Station is equipped with radio-echo apparatus similar to that at the Jodrell Bank Experimental Station at the University of Manchester, England. Although echoes occur much more frequently at the Antarctic station, their general features appear to be the same at both stations.

No correlation was found between specific auroral forms and the sharpness of the radio echoes. Moreover, the fact that echoes are not always received when quiet arcs are present suggests that ionization of sufficient density to cause reflection is associated only with the more active auroral forms.

Comparison of the Halley Bay radio-echo data with similar data for the same period at Jodrell Bank suggests the conclusion "... that the great aurora of the northern hemisphere are accompanied simultaneously by a greatly enhanced activity of the aurora australis."

Comparison of auroral data with magnetic data: Since the Royal Society Station is some distance from the auroral zone, auroras are usually highly active by the time they have moved overhead. This hinders direct correlation with simultaneous magnetic disturbances. Nevertheless, the report states, "There are ... indications that the vertical magnetic disturbance force does not change sign when arcs and draperies pass through the zenith, as should happen if the magnetic disturbance is due to an east-west current flowing along the base of the arc. On the contrary, large vertical disturbances were sometimes observed when a drapery passed overhead. More detailed analysis will be necessary before any definite conclusions may be drawn on this point."

Ionospheric Physics

The program is in general being carried out as planned and the flow of data to the World Data Center C subcenter for Ionospheric Data, at Slough, England, is rapidly increasing. A large volume of all types of ionospheric data has been received from the Royal Society Station in the Antarctic.

Ionospheric measurements at Halley Bay indicate that the station is situated outside the auroral zone. The main features of the daily F-layer variation (layer which reflects high-frequency radio waves) over Halley Bay were:

"(a) . . . very large diurnal variation in the electron density with a maximum near noon in winter despite the absence of significant photo-ionization from the sun.

"(b) . . . suddenness of the change from typical winter to typical summer variations which occurs near the equinoxes.

"(c) . . . small diurnal variation in the electron density in summer which shows a maximum near midnight and a minimum near noon.

"These features are consistent with the hypothesis that the diurnal variations of the F2 layer at Halley Bay are mainly determined by movements of ionization and not by the primary photo-ionization processes."

The report further states that winter-month ionograms show two distinct reflecting structures in the F region ". . . at times between about 1900 LMT [Local Mean Time] and 0200 LMT. One of these is continuous with the dense layer present on the previous noon and the other, . . . first seen at oblique incidence, gradually replaces the former and eventually develops into the dense F layer of the subsequent noon period. The new structure is sometimes first seen at appreciably lower heights than the old F layer and it then gives rise to striking discontinuities in the diurnal variations of the density and height of the layer. . . . The earth's magnetic field at Halley Bay shows unusual fluctuations while this movement is taking place. . . . The new layer is generally dominant before the . . . main period of corpuscular activity, . . . between 0200 and 0900 LMT, and . . . the noon F2 critical frequencies in midsummer and midwinter are practically equal."

In the vicinity of the Royal Society Station, there appears to be very good correlation between auroral and ionospheric activity. Preliminary reports indicate that auroras occurring at the zenith are accompanied by severe radio blackouts.

Daily radio-wave absorption measurements indicate the presence of a sporadic, corpuscle-controlled absorbing layer in the ionosphere along with the normal, solar-photon-controlled absorbing layer. This sporadic layer is densest and occurs most frequently near 0400 LMT, the time of maximum occurrence of total blackouts. Moreover, the daily variation of the sporadic layer is similar to that of the blackouts.

Considerable activity is also shown at 0400 LMT by the radio-echo index, but its daily variation is, in general, shifted to earlier hours. This was unexpected, as similar measurements in the northern hemisphere show a shift to later hours.

Solar Activity

A heliograph for analysis of the Hydrogen-alpha radiation of the sun commenced operation at the Cape of Good Hope in March 1958. This instrument is providing full information for about 30 solar flares each month. The films produced by the heliograph are being analyzed photometrically, and light curves have been prepared for a number of solar flares.

Rockets and Satellites

As the program progressed there was a substantial expansion of effort in the field of rockets and satellites.

Satellites: Working groups on optical (visual and photographic) and radio (including radar) tracking were set up and arrangements made for observation of earth satellites passing over the United Kingdom. Similar arrangements were made at the University College of Ibadan, Nigeria, and at the Radio Research Substation, Singapore.

The photographic and visual observations are being made both at observatories and by amateur astronomers. Radio observations, including doppler studies, and signal-strength measurements have been made at nine or more stations; interferometers and direction-finding equipment are also in use at these stations. Radar observations have been made at Jodrell Bank. Telemetry equipment for recording data from United States earth satellites, loaned by the US-IGY Committee, is operated at Ibadan and Singapore; telemetry signals from USSR satellites have been recorded by the BBC receiving station at Tatsfield, England, and by amateur radio observers.

United Kingdom agencies are issuing orbital predictions for earth satellites.

Rockets: A high-altitude rocket, the "Skylark," has been developed for upper-atmosphere research. Following the first IGY launching at Woomera, Australia, on April 17, 1958, several successful additional launchings have been made. Although the results are still being analysed, "... one interesting phenomenon, believed to be due to the presence of atomic oxygen, is the development of an intense luminescent cloud lasting 3 to 4 minutes from the explosion of the highest sound-ranging grenade at about 120 km [75 mi], ... it is hoped in further experiments to study wind distribution by this means."

Seismology

In Britain, a number of stations are compiling and transmitting seismic data, including observations of microseisms. Eight stations in the West Indies, the Royal Society Station in Antarctica, and a station at Port Stanley, Falkland Islands, are also contributing data.

Small earthquake shocks are recorded frequently at the Royal Society Station. These appear to be local, possibly associated with mountains within a few degrees of the station. According to the United Kingdom report, "No other seismic activity has been traced to the Antarctic continent."

Gravity

A gravity traverse was carried out during the Commonwealth Trans-Antarctic Expedition from Shackleton Station (UK), on the Weddell Sea, via the South Pole to Scott Station (NZ), on McMurdo Sound. Measurements of relative gravity were made with a Worden gravimeter after each camping period and at intervals of about 15 mi along the 2150-mi traverse route. Similar measurements were made at the Royal Society Station.

With US cooperation, the Cambridge University Department of Geodesy and Geophysics made a series of pendulum gravity measurements early in 1958 at eight stations between Teddington, England, and Johannesburg, South Africa. Another such series was planned for 1958 between Washington, D. C., and South America.

Earth tides are being recorded continuously at Winsford, Cheshire, England. The records are sent to Bidston Observatory for reduction and analysis.

B. Antarctic Notes

The following review of plans by 12 nations for scientific activity in Antarctica during 1959 is based on a report in the CSAGI publication, IGY News. *The information for the report was supplied by the Acting Secretary of the Special Committee on Antarctic Research (SCAR) of the International Council of Scientific Unions (ICSU). In general, it appears that research activity in the Antarctic during 1959 will continue at nearly the same level as that maintained during the IGY, which ends on December 31, 1958.*

Argentina: The scientific program at Ellsworth Station will be continued cooperatively by Argentine and US personnel; two US meteorologists will winter-over at Ellsworth Station in 1959 and remain through the 1959–60 Antarctic summer season. The program at General Belgrano Station, on the Filchner Ice Shelf, will continue on a limited basis; other Argentine Antarctic stations will continue at present levels.

Australia: The Macquarie Island, Mawson, and Davis Stations will be maintained. In addition, the program at Wilkes Station will be continued cooperatively by Australian and US personnel; two US meteorologists and one US biologist will be at the station through the 1959 winter and the 1959–60 summer seasons. Oversnow traverses will be conducted from Mawson during the 1958–59 summer season; they will then be transferred to Wilkes Station.

Belgium: The Roi Baudouin Station will remain in operation during 1959.

Chile: All present stations will be maintained in 1959, and the Risopatron Station, destroyed by fire in March 1958, will be rebuilt. Additional studies in geomagnetism, cosmic rays, geology, chemistry, biochemistry, and bioclimatology are planned.

France: The inland Charcot Station will be closed at the termination of IGY, but the D'Urville Station, on the coast, will continue to operate with only slight reductions in parts of the program.

Japan: Reoccupation of Syowa Station by a wintering-over party of 12–15 men is planned for February 1959. (The station was evacuated in the summer of 1957–58 because ice conditions made resupply impossible.) The party will resume the original program of observations in aurora and airglow, cosmic rays, geomagnetism, ionospheric physics, meteorology, glaciology, and seismology.

New Zealand: The program at Scott Station will continue; four US scientists will winter-over during 1959, remaining through the summer of 1959–60. Hallett Station will be operated jointly with the United States on a modified basis. The 1958–59 summer program will include studies in biology, geology, and oceanography; topographic surveying will also be carried out.

Norway: The present scientific program at Norway Station will continue in 1959.

South Africa: There are tentative plans to continue investigations on the Tristan da Cunha Islands, on Marion Island, and, subject to agreement with the United Kingdom, on Gough Island.

United Kingdom: Research in the major scientific disciplines will continue at Royal Society Station; eight other Antarctic stations will continue present programs. Extensive topographic and geologic surveys will continue in the Graham Land region, at the northwestern end of the Palmer Peninsula.

United States: Full operations will continue at the Byrd and South Pole Stations; at the Naval Air Facility, McMurdo Sound; and, in cooperation with New Zealand, at Hallett Station. Oversnow traverse operations will continue; they will be made primarily in Marie Byrd Land, but one is planned for Victoria Land during the 1958–59 summer season. Little America Station will remain in use for some purposes.

Soviet Union: All stations will be maintained except Pioneerskaya, which will be closed in January 1959. The program at Bunger Oasis will be reduced. It was hoped to transfer Sovietskaya Station to the "pole of inaccessibility" during October–November 1958. Additional traverses are planned, including one from Vostok Station to the US-IGY South Pole Station and back to Sovietskaya during the 1959–1960 summer season. It is also planned to establish additional small bases—one south of the Bellingshausen Sea and one in Queen Maud Land—for glaciological and meteorological studies and to assist in future traverses. Oceanographic investigations will continue in the Bellingshausen Sea and in the Antarctic Convergence region, to the north, as well as along the coast of Queen Maud Land.

Auroral Storm of February 10–11, 1958

The following report is based upon material supplied by J. R. Winckler, L. Peterson, R. Hoffman, and R. Arnoldy, School of Physics, University of Minnesota.

During the night of February 10–11, 1958, a very large auroral storm occurred. The storm and other related phenomena were especially well observed and reported, both visually and by a number of instrumental techniques.

Balloon-borne instruments at Minneapolis detected two groups of strong X-ray bursts during the storm. These coincided with two large magnetic bays (increases or decreases in the intensity of magnetic-field components, represented by bay-like indentations on graphs showing variations of magnetic intensity with time); with strong absorption of radio noise; and with the passage across the zenith of a very large amount of auroral luminosity. A cosmic ray decrease also accompanied the storm.

The University of Minnesota workers believe that these terrestrial disturbances were associated with the earth's entry into a large cloud of solar gases that may have originated in a solar flare occurring about a day earlier.

The Aurora

The aurora observed in North America during this storm was one of the most spectacular in recent years. It was reported as far south as Cuba. At Minneapolis, the aurora was seen by visual observers simultaneously with the sudden commencement of the magnetic disturbance, at 0126 UT February 11. The all-sky camera record from Hanover, N. H., shows its appearance a few minutes after the magnetic disturbance began. At Minneapolis, from 0130 to 0330 UT a very intense diffuse green arc covered the sky from 20° above the northern horizon to the zenith and from the eastern to the western horizon. The outstanding feature, however, was the red color, also very intense, which appeared in diffuse patches at high angles above the northern horizon and, at 0200 UT, covered the northern sky from 15–30° elevation as a diffuse arc.

The IGY Auroral Data Center at Cornell University has supplied the following table showing the southern limit of arc forms at one-hour intervals:

UT Feb. 11	00	01	02	03	04	05	06	07	08	09	10	11	12	13
Geomagnetic N Lat.	58	54	50	49	51	48	47	52	50	50	46	48	53	54

It is estimated that the aurora extended from a height of about 200 km to 800 km, and for a distance of about 9600 km east-west and 400 km north-south. In addition to the very high intensity of both the red and green spectral lines, other unusual features of the aurora were the diffuseness and extent of the luminescence, and its persistence for long periods without major changes in form.

Auroral forms or high auroral luminosity were also observed visually or recorded by all-sky cameras at Minneapolis, Fargo, N. D., and Yerkes Observatory, Williams Bay, Wisc., twice during the second phase of the storm. On the first occasion, movement was northward. On both occasions—beginning at 0620 and 0848 UT—they were exactly coincident (on the order of one minute) with the appearance of X-ray bursts, magnetic bays, and cosmic-noise absorption.

Related Solar Phenomena

Considerable solar activity was present for several days prior to the terrestrial storm; hence, the solar-terrestrial relationship is not completely certain. However, the outstanding solar event of the period was a flare, reported by Honolulu Observatory as Class 2; it started at 2108 UT February 9 and ended at 2302 UT the same day, with maximum phase at 2140. The flare was also observed by Sacramento Peak Observatory (N. Mex.), which classified it as 2+. Large radio-noise fluxes were reported by several stations during the flare.

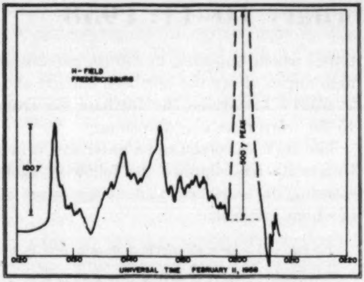

Fig. 1. *Trace of Rapid-Run Magnetogram at Fredericksburg Observatory for First Part of Auroral Storm of February 10–11, 1958. The 500 γ peak was accompanied by large earth-current disturbances.*

Magnetic Storm Phenomena

The terrestrial effects of this storm began at 0.125.7, ± .2, UT on February 11, according to the rapid-run magnetogram of Fredericksburg (Va.) Observatory. (Figure 1 shows the record of this instrument for the first phase of the storm.) The horizontal component (H) of the earth's magnetic field immediately showed a bay of $+117\gamma$ (one gamma, γ, equals 1/100,000 gauss; the earth's total magnetic-field strength is about ½ gauss in middle latitudes). A second sharp, positive bay appeared at 0159.0, ±.1; it followed a disturbed period and was larger than the first, reaching a peak value estimated at about $+500\ \gamma$. This sudden increase in the horizontal component (H) was accompanied by sharp drops of about 150 γ in the vertical component (Z) and 30 γ in the magnetic declination (D). It is assumed that these pulses represent the initial encounter of the solar gas cloud with the earth's dipole field, the sudden appearance of ionospheric current systems, or both. If one assumes a relative speed between the earth and the solar stream of 1400 km/sec, then a time lapse of 0.1 min for an appreciable change in H to occur corresponds to a relative movement of the solar stream of about two earth radii.

If the sudden commencement of the magnetic disturbance is associated with the solar flare that occurred at 2108 UT on February 9, the transit time is approximately 28 hours, indicating a speed of 1400 km/sec. This speed lies within the range of values often postulated for solar corpuscular streams. In addition, the over-all strength of the storm field, with bays of 1000 γ, below the auroral zone, classifies this storm as an extreme one.

Earth Currents: Large earth currents were observed coincident with the horizontal-component peak at 0159. A communication from T. E. Talpey, of the Bell Telephone Laboratory, Murray Hill, New Jersey, states that the earth's potential at the western end of the North Atlantic Telephone Cable dropped from a maximum of about 2650 volts at 0202 UT on February 11, through zero to a peak in the opposite direction at 0209 UT. The current was being driven from west to east through the cable. The section of cable between Clarenville and Sydney Mines, Nova Scotia, at about the same times as the peaks at the western end of the trans-Atlantic section, exhibited peaks of 1450 and, in the opposite direction, 1100 volts. The cable from northern Washington State to Alaska had a maximum of only 250 volts, and the California-Hawaii cable showed no major voltage changes.

The observed earth current peak seems to be an induction effect associated with the second, and largest, of the two magnetic peaks. According to the observations, the recorded current flow was from west to east, H increased, and Z decreased. The total storm field is a north vector increasing initially. The circuit loop of the earth current, if considered to lie in a vertical east-west plane, requires a return path through the sea *above* the cable. However, derivation of the potential in the water gives only about 15 volts around the circuit, compared to the measured maximum of 2650 volts. (The circuit cannot be closed *under* the cable as the polarity would be wrong for an induction effect associated with the horizontal-component bay.)

It is felt, therefore, that the earth current is apparently part of a system flowing in the earth's surface and associated with changes in the vertical component in an unexplained way. The current system seems to be centered over the eastern United States.

Remainder of Storm: The remainder of the magnetic storm was characterized by two large negative bays in the horizontal component (see Fig. 2). The bays were closely associated with the sudden appearance of intense auroral activity passing the zenith in the vicinity of Minneapolis.

Balloon Observations of Auroral X-Rays

Following the discovery of X-rays penetrating to balloon altitudes at Minneapolis during auroral storms on three occasions in 1957 (see *Bulletins 10* and *15*), attempts have been made routinely to prepare launchings when strong storms are forecast. A balloon launched at 0445 UT on February 11 encountered the first detectable X-ray bursts at 0622, coincident with the major decrease in the first large magnetic bay of the second phase of the storm; these bursts continued until 0730. A second large period of bursts occurred at 0850, coincident with the second magnetic bay of this phase (Fig. 2).

It is thought reasonable to assume that both the changes in conductivity of the ionospheric E-layer, which produced the magnetic bays, and the observed X-rays had a common origin in electrons produced by the solar gas stream. These electrons may be accelerated several earth radii from the earth by an interaction between the earth's dipole field and the neutral plasma from the sun. Their energies would lie in the range from 40–100 kv or higher; most of their energy, however, would be lost in the atmosphere as ionization and as the visible auroral light. About 1/1000 of the energy would be radiated as Bremsstrahlung X-rays (see *Bulletin No. 10*) the higher-energy components of which are detected at balloon levels (about 100,000 ft).

Cosmic Noise Absorption

The large absorption of cosmic radio noise at 18 megacycles/sec was observed exactly coincident with the magnetic bays and the X-ray bursts. The absorption was observed, at Boulder, Colorado, both with a vertically beamed antenna and with an interferometer

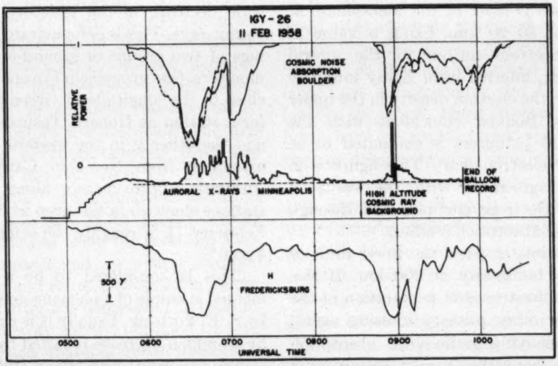

Fig. 2. *Comparison of Measurements of the Horizontal Component of the Magnetic Field at Fredericksburg, Auroral X-Rays at Minneapolis, and Cosmic-Noise Absorption at Boulder. Intense, widespread ionization appears to have occurred twice, at approximately 0630 and 0900 UT.*

directed at an elevation angle of 35° to the northeast. The similarity of the records is good evidence for a very widespread increase in ionospheric electron density extending north-south for at least 150 km. Heavy overcast at Boulder prevented direct observations of the aurora, but the correspondence, even in fine detail, of the fluctuations of the output of the two antennas implies simultaneous fluctuation of the primary phenomena over distances of hundreds of kilometers. Furthermore, the correspondence of data among Fredericksburg, Minneapolis, and Boulder (Fig. 2) shows that the major primary fluctuations were simultaneous over distances of thousands of kilometers.

Correlation of X-Rays, Magnetic Bays, and Cosmic Radio-Noise Absorption

The large changes in the magnetic-field H component, the strong cosmic-noise absorption, the auroral X-rays, and the general presence of the aurora itself, are all consistent with a very intensified bombardment of the ionosphere by high-energy electrons between 0530–0700 UT and 0830–0930 UT on February 11 over central United States.

It is assumed that cosmic-noise absorption during an auroral storm occurs mainly in the upper D-layer of the ionosphere, at altitudes of 80–90 km. Using a value of 6×10^6 electrons/cm^2/sec for the auroral electron flux, inferred from X-ray intensity and energy, the electron density in the upper D-layer at Boulder coincident with the February 10–11 aurora is computed to be 1.2×10^5 electrons/cm^3. This figure is in reasonable agreement with the value of 1.4×10^5 electrons/cm^3 obtained through cosmic-noise-absorption studies.

Visual estimates place the lower limit of the auroral luminosity at 200 km. If this marks the lowest level of penetration of the electrons or other primary ionizing agent, the accompanying radio-noise absorption must arise from the X-rays acting as a secondary ionizing agent—penetrating to much lower levels, ionizing the E and D layers, and appearing at balloon heights. Only 10^{-3} to 10^{-4} of the electron energy appears as Bremsstrahlung X-rays and only high-energy X-rays reach balloon levels; hence, the X-ray energy falls far short of the amount needed to account for the D-layer electrons causing the cosmic-noise absorption. Therefore, either the estimated height of 200 km was too high and the lower border of the aurora was actually at the usual height of 75–100 km, or electrons or other particles carried considerable energy downward, below the visual auroral border. Possibly, the visual luminescence is associated with protons at higher levels, while electrons constituting an equal or nearly equal current penetrate to lower levels producing the ionospheric effects without large amounts of visual luminosity.

The large magnetic bays observed at Fredericksburg coincident with the X-ray bursts may be attributed to an increased conductivity of the ionospheric E-layer, owing, probably, to the same ionizing agent that produced the cosmic-noise absorption phenomena.

Cosmic Ray Phenomena

The storm was accompanied by a worldwide decrease in the intensity of galactic cosmic rays. This is demonstrated by recordings of two groups of ground-level neutron monitors. One group is in Europe and Africa, close to the longitude of Greenwich, except for a station at Hobart, Tasmania (145°E), and the other is in the western hemisphere extending from Northern Canada to the Antarctic approximately along 90°W. All stations show an initial drop at 0200 UT on February 11 of roughly the same amount—4 to 6%.

(This is considered to be a well-documented example of a phenomenon discovered by S. E. Forbush. Usually it is characterized by a sudden decrease followed by a slow recovery requiring several days, and frequently much longer periods. Although the decrease applies to all energies of primary cosmic rays,

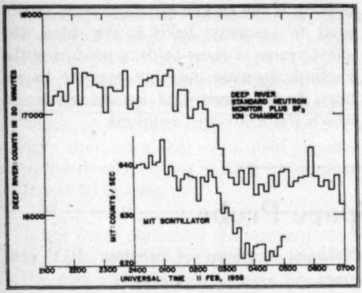

Fig. 3. *Cosmic-Ray Counting-Rate Records for Neutron Monitor and Ion Chamber at Deep River, Canada, and for Scintillation Counter at the Massachusetts Institute of Technology. The "precursor" appears at 0127 UT; the major decrease begins at approximately 0200. Canadian information by courtesy of Hugh Carmichael; scintillator information from Palmeira and Williams,* Il Nuovo Cimento, *Vol. III, 1958, p. 352.*

the low-energy part of the spectrum is affected to a larger extent than the high.)

Another feature of the Forbush-type decrease, which seems to have been reported for the first time in this event, is a "precursor" drop in intensity that occurred closely coincident with the sudden commencement of the magnetic storm, at 0127 UT. As shown in Figure 3, the precursor drop is about 0.5% in the scintillation-detector record and 1% in the neutron-monitor and ion-chamber record. Both records show an apparent increase in intensity just before the precursor. The major decrease occurred between 0200 and 0330 UT and was completed by the end of the "first phase" of the magnetic storm, at the same time that H at Fredericksburg (Figure 1) dropped below the prestorm level.

High altitude soundings with a standard ion chamber and counter were taken before, during, and after the decrease. The total influx of cosmic-ray energy, obtained by integrating the ion chamber rates throughout the atmosphere, dropped 14.9% during the storm; by February 16 it had recovered to within 8.4% of the February 8 value.

Discussion

All the phenomena described are consistent with the passage of the earth into a remarkably intense solar cloud. This cloud may have originated in the solar flare beginning at 2108 UT February 9 and ending at 2302 UT February 9. According to the magnetic records, the terrestrial disturbances began at 0127 UT February 11, and by 24 hours later had fallen to a low level. It may be assumed that the earth was clear of the cloud by that time.

If the cloud originated within the two-hour interval of the flare and required 24 hours to pass the earth, considerable velocity dispersion must have been present in the solar gas. The velocity range of particles in the cloud must have been about 700 to 1400 km/sec, and the radius of the cloud when passing the earth about 0.5 astronomical units (the distance from earth to sun). The minimum lateral extent, estimated from the angular position of the flare with respect to the sun-earth line, was about 0.25 astronomical units near the earth.

The velocity dispersion requires that the slower solar particles predominate later in the storm. The leading edge of the cloud must have been exceedingly well defined and on the order of an earth radius across. The cloud must also have contained considerable internal structure, as revealed by the "spikes" in the first phase and by the two large bays accompanying the X-ray bursts later in the storm. These structural features must have persisted during the sun-earth passage despite the large velocity dispersion.

The process of tracking these features back to a specific series of events in the flare would be extremely difficult. Nevertheless, it is possible to conclude that either the flare emitted considerable matter in very discrete velocity groups, or that a non-linear propagation effect intensified certain portions of the stream, in particular the leading edge and several internal regions.

This storm is unique with respect to the great intensity of the associated ionospheric phenomena; this may reasonably be attributed to an exceptionally high density of the solar gas enveloping the earth. In contrast, the modulation of galactic cosmic rays, while appreciable, is in no way exceptional when compared with other Forbush-type decreases. If the cosmic-ray decrease is attributed to magnetic fields in the cloud, the effectiveness of these fields in producing the Forbush decrease does not seem to be related to the amount of ionized matter in which the fields are contained.

First Deep Space Probe

The first probe into deep space was launched from Cape Canaveral, Florida, at 3:42 pm EST on October 11, 1958. Though it did not reach its maximum objective, the environs of the moon, the space probe, named Pioneer, reached a record altitude of approximately 72,800 mi (63,200 nautical mi) and telemetered much scientific information to earth.

The probe was launched by the Air Force Ballistic Missile Division, under the direction of the National Aeronautics and Space Administration, as a contribution to the National Academy of Sciences' IGY program.

Launching: The launching vehicle was a four-stage rocket with a total length of 88.1 ft and weighing approximately 112,000 lbs. The first stage, or booster, was a standard Thor, about 61 ft long, 8 ft in diameter, and weighing approximately 106,600 lbs. It develops about 150,000 lbs of thrust. The second stage was a modified Vanguard second stage, a liquid-fueled rocket 18 ft long, 32 inches in diameter, weighing 4612 lbs. I

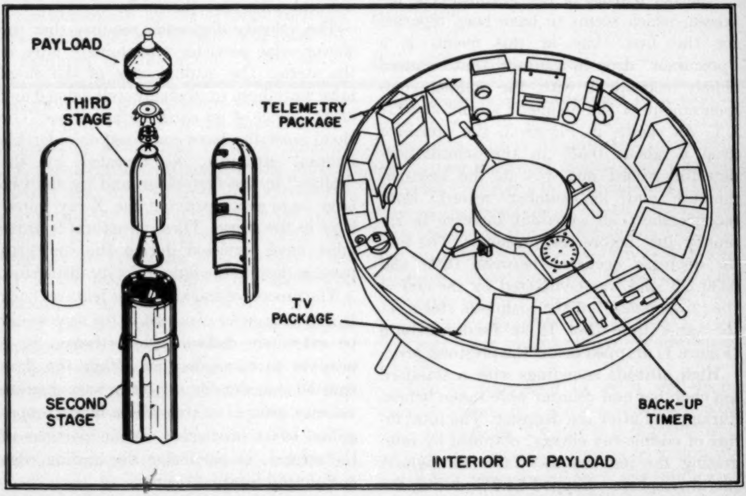

Fig. 4. *Upper Stages and Payload of Pioneer Space Probe. Prepared by Space Technology Laboratories.*

develops a thrust of 7700 lbs. The third stage was an advanced version of the Vanguard third stage, a solid-propellant rocket five ft long, 24 inches in diameter, weighing 597 lbs, and developing about 3000 lbs of thrust. A fourth or terminal stage, to be fired 2.61 days after launching, was a solid-propellant rocket developing up to 2200 lbs of thrust. It was 30 in long.

Eight small vernier rockets were attached to the lower portion of the terminal vehicle to impart velocity and vector corrections to the payload immediately after burnout of the third stage. Spin stabilization of the payload was accomplished by means of spin rockets.

A velocity of 35,250 ft/sec had been planned for the probe. However, because Pioneer traveled about 3.5° above the designed flight path, the actual velocity attained was about 34,400 ft/sec.

Payload characteristics: The toroidal-shaped payload, pierced by the terminal-stage rocket, was 29 inches in diameter and weighed 85 lbs (see Fig. 4). The weight of the instrument package itself was approximately 39 lbs. Pioneer was constructed of Fiberglas, and was painted in a special pattern as a means of controlling temperatures.

Instrumentation: Pioneer carried instrumentation to measure radiation encountered in space; the magnetic field of the earth and of the moon; density of meteoric matter in the payload's flight path; temperatures within the scientific package; and to obtain a crude electronic picture of the surface of the moon—the so-called TV scanner.

The ion chamber used to measure radiation was built to a design developed by James A. Van Allen and Carl E. McIlwain at the State University of Iowa. The Air Force Cambridge Research Center designed the micrometeorite equipment, which was built by the Space Technology Laboratories. STL, designer and producer of Pioneer, had responsibility for over-all scientific direction of the probe. STL also developed the magnetometer and temperature experiments. The scanning system was developed by the Naval Ordnance Test Station, China Lake, California.

Preliminary inspection of the scientific data by Van Allen and his associates at State University of Iowa indicates that the probe may have traversed the Van Allen radiation belt as it penetrated into space; temperatures within Pioneer remained within the range of human survival, if not comfort. More detailed reports of these and other experiments will be made available to the scientists of the world as soon as possible.

Tracking: Five prime stations tracked the Pioneer. They are located at Manchester, England (the Jodrell Bank radio telescope of the University of Manchester); Singapore, Malaya; Hawaii, T. H.; Cape Canaveral, Florida; and Millstone, Mass. All but the Singapore station were equipped to obtain positional data on Pioneer, and all stations recorded telemetry data. These stations, and the NASA Minitrack stations (via the NRL operations center at Cape Canaveral), funneled their information to the Data Reduction Center of STL at Inglewood, California.

The Hawaii prime tracking station was last to have contact with Pioneer, at 10:46 pm EST, October 12, 1958, as it fell back toward the earth. The probe presumably disintegrated in the earth's atmosphere over the South Pacific shortly thereafter.

IGY Bibliographic Notes

This is the fifth of a series of bibliographic notes on IGY programs and findings. The references are selected largely from an IGY bibliography under preparation in the Science and Technology Division of the Library of Congress.
